**6. Continental Climates.**—Continental climates exhibit conditions the reverse of those which obtain in maritime climates. The tendency is to cold winters and warm summers, owing principally to the absence of the equalising influence on temperature of large masses of water. A very short distance from the sea is sufficient to establish this difference. Thus the central parts of France are very much warmer in summer and colder in winter than the coasts of Normandy and Brittany. But it is when we reach the centre of continents—Russia, Central Asia, Central America—that the difference is the most marked.

**7. Mountain Climates.**—As we rise above the level of the sea, we meet with two important meteorological conditions. The air becomes more and more rarefied, and the heat diminishes, independently of the more or less obliquity of the sun's rays. The higher we rise above the sea-level the more the air is rarefied, and the more the degree of heat due to the solar rays diminishes. We arrive at last, even at the tropics or the equator, at a height, variable according to

latitude, where the sun's heat is insufficient to melt the snow. This is termed the snow-line. Mountains attract clouds and watery vapour, and the coolness of their atmosphere causes the precipitation of the vapour in the form of rain or snow. Thus, mountains, mountain-ranges, and the glaciers they contain, are the principal cause and origin of rivers.

*The influence of mountain climates, notwithstanding the clouds, fogs, and rain which characterise them, is proverbially a healthy one, owing to the purity of the air, the shelters found in the valleys, and, perhaps, to the sparseness of population. They have of late been much recommended for phthisis. The conditions above mentioned, together with sunshine to a limited extent, are quite sufficient to account for the rarity of phthisis amongst their inhabitants, and for the improvement of the phthisical who resort to them.*

*Soil modifies climate considerably. Wet and marshy soils are cold, engendering fog and mist. Sandy, dry, well-drained soils are comparatively warm. All sandy plains are warm in summer and cold in winter.*

Such are the features which characterise the climates of the terrestrial globe, generally. Each locality, however, each mountain, plain, and valley, each city, village, and house has a climate of its own, modified by all the meteorological elements which we have successively considered. To discover what each climate is, we must study carefully the meteorological conditions and influences which we have rapidly surveyed in their application to it.

*Isothermal Climates.*—Owing to the unequal influence of the different elements that constitute climate, the annual mean temperature of regions occupying the same latitude on the earth's surface is very variable. Hence the above name has been given to the regions in which the annual mean is the same. The study of a map on which the isothermal lines are marked is an instructive illustration of the facts above described. Thus it will be seen at a glance that the limit of constantly frozen ground in the central plains of Asia and in the northern plains of America is below  $54^{\circ}$ , which is the latitude of York!

**THE GENERAL INFLUENCE OF CLIMATE.**—The vegetable and animal worlds, including man himself, have been modified in essential characters by climatic conditions. The study of its influence on their vitality and organisation opens out a wide field to the observer. This study leads to the conclusion that geological periods of time have been necessary to impress on terrestrial life, be it vegetable or animal, the characteristics observed now or formerly in the climates of different regions of the earth. The current of modern research is strongly directed to the elucidation of the

influence of climate on life during such geological periods. The investigations of Darwin and his followers may be named as the most remarkable and important illustration of this fact. We may also mention the researches of modern philologists, which have proved, by the study of languages and their roots, that most of the nations of modern Europe have descended from the same Aryan parents as the inhabitants of the Indian peninsula. Climate, in the course of time, has so modified them as apparently to produce different races. For such a change to take place geological lapses of time are certainly required. Our earliest records, dating back several thousand years, show these races, such as they are now, quite as distinct. In these days the Aryan races of Europe cannot rear their children in the climate of India, where their Hindoo relatives thrive and propagate their species. In Palestine and Egypt the biblical records, those of the Pharaohs, and those of Nineveh and Babylon, show these regions to have been inhabited, several thousand years ago, by nations and tribes presenting precisely the same race characteristics as those that now inhabit them. During the historical period, the races of Europe have in vain endeavoured to colonise the valley of the Nile; for they have not been able to propagate their species, and have died away, leaving the valley of the Nile to its ancient inhabitants. Their children cannot withstand the heat of summer. On the north-eastern shore of Africa, the Algeria of the present, history presents the same record. The Romans and the Visigoths occupied its plains for centuries, continually recruiting their colonies from the mother-countries; and yet, except in the mountains, all trace of their presence has disappeared. They could not rear their children so as to occupy the land of the Arabs. What lengthened periods of time must have elapsed to so profoundly modify races deriving their origin from a common parentage, that they can no longer live and propagate their species in the same climates!

**THERAPEUTICAL APPLICATIONS.**—The therapeutical application of many of the above facts is contained in the facts themselves. Reasoning suffices to deduce the therapeutical law, and experience proves the correctness of the deduction. Only a very brief summary can here be given. See also **CLIMATE, Treatment of Disease by.**

Firstly, it is clear that if a local climate produces injurious effects on the health of its inhabitants, or of visitors, the latter should leave it, and the regular inhabitants, who cannot leave it, should endeavour by every possible means to modify the pernicious climatic influence to which they are exposed, and to partially escape from its action. This rule may be illustrated by the influence of confined mountain valleys in producing

goitre, and of marshy districts in producing intermittent fevers. The principle applies to all local climates which exercise a pernicious influence of any kind on the human organisation. When possible the climate should be abandoned; if that is impossible, its pernicious influence must be combated by every possible hygienic and therapeutical means.

The injurious effects which extreme climates exercise on the human economy—warm climates on the abdominal and cerebral organs, cold climates on the thoracic—point to change of residence as an important therapeutical agent, the value of which is only beginning to be understood. Our naval and military surgeons have done much to clear up this branch of therapeutics, as regards the diseases of tropical regions. Thus chronic affections of the liver and intestines, incurable in a warm climate, often become quite curable if the patient is transferred to a temperate region or to a mountain elevation in the tropics, which reproduces a temperate climate.

Inversely, persons suffering from diseases of the respiratory organs, so common in damp temperate climates like those of France, England, and Holland, find relief by migrating, especially during winter, to warmer regions of the earth's surface, where they escape from the influences which have proved so detrimental to them. Thence the yearly increasing exodus of persons suffering from chronic laryngitis and bronchitis, from bronchial asthma and from phthisis, from the north of Europe to the south.

The increased facilities of locomotion, by rail and by steam, have thus opened out, as it were, a new and important branch of therapeutics, that of the application of climate to the treatment of disease.

J. HENRY BENNET.

**CLIMATE, Ætiology of.**—See DISEASE, Causes of.

**CLIMATE, The Treatment of Disease by.**—Though we can scarcely say with accuracy that change of climate is a specific for disease, yet much can be effected by it in relieving symptoms, and in assisting the recuperative powers of the organism by thus improving the general health. The diseases in which change of climate has been found of value will be enumerated below, with a short notice of various climates. Here we may notice the *rationale* of the benefit to be derived from such change.

Change of climate, we must premise, is only a relative term. It does not necessarily involve the idea of removal to a great distance from the patient's home. A few miles' journey from the town to the country, from inland to the seashore, from the plain to the mountain, often suffices to produce marked results. One use of climate being to expose

the organism to the effects of *contrast*, the element of distance comes in most when we wish to make the contrast greater; for instance, in ordering change from a cold to a warm climate or *vice versa*.

The therapeutical elements of most importance in any climate are: (1) pure air, free from dust and organic particles, or excessive damp; (2) abundance of sunshine, without excessive heat, so that much time can be spent in the open air; (3) a temperature without extremes, so that the body is not exposed to the risk of great variations of heat and cold—equability; (4) absence of violent, very cold, or very hot winds, at any rate of long duration (in this is involved the element of local shelter).

These four elements should be present in each of the subdivisions of climates which a therapeutical classification renders necessary, namely, climates of: (1) *the seashore*; (2) *mountains*; (3) *inland wooded districts*; and (4) *the open sea*.

The epithets 'moist' and 'dry,' which are applied to climates, are merely relative, and depend on local peculiarities of rainfall, soil, &c., as well as to some extent on season; and the essential differences between the climate of the seashore, the woodland, and the mountain remain everywhere the same. We shall say a few words about each of these, with the indications for their use. The climate of the open sea will be referred to in speaking of sea voyages.

**1. Climate of the Seashore.**—The special peculiarities of this variety of climate are that the air is saturated with moisture, except when dry land winds prevail; it is dense, and, as a rule, therefore, bulk for bulk, contains more oxygen than air of any higher level; its density is liable to great and frequent but regular variations, which increase the activity of the circulatory and respiratory organs, and thus favour their functional activity; it is more equable; and, lastly, it contains saline particles in suspension.

According to Beneke, sea air cools the body relatively more quickly than mountain air, and thus hastens more the processes of tissue-change. Hence, the seaside should be ordered where we wish for a highly stimulating effect, as in persons of scrofulous tendency, in chronic succeeding acute diseases, or in the later stages of convalescence from the latter, in convalescence from surgical operations, or in some surgical diseases where we wish to accelerate tissue-change, without exertion on the patient's part. On account of the equability of the climate, some patients who cannot bear great changes of temperature do well at the seaside. Persons suffering from overstrain, mental or bodily, with a fair digestive power, and not liable to nervous irritability, may also be sent there.

**2. Mountain Climates.**—Mountain climates are distinguished from seaside climates by the lower density of their atmosphere; their lower and less equable temperature; by less humidity, though, owing to local winds, mist and cloud often form; and by relatively lower night-temperatures in clear weather, owing to the dryness of the air, and consequent great radiation. They are cooler also than the inland climates of level districts, and this coolness tends to some extent to diminish the rarefaction and increase the density of their air.

The general action of mountain air is to produce a freer circulation of the blood and greater vascularity of the lungs, owing to deeper and more frequent inspirations and greater ease of bodily movement. Owing to the cooling of the body by the lowered temperature more food is required. The appetite improves, and the body becomes better nourished and gains weight.

The intensity of the effect is, broadly speaking, directly as the height. The term 'mountain climate' is applied in medical parlance to elevations in Europe of from 1,500 to 6,000 feet, though in South America patients have been sent as high as 10,000 feet, or higher.

Mountain climates are indicated: (1) in cases of hereditary tendency to phthisis in young persons with narrow, shallow chests, who are growing too fast; also in young scrofulous patients. (2) In chronic phthisis and pneumonia; remembering, however, that phthisis occurs at all elevations. The coolness of the mountain air in the height of summer is an important element in phthisical cases, which always suffer from great heat. (3) As a tonic and restorative in persons suffering from over-work in business or literary pursuits, and who have no real organic disease. (4) Generally to complete the convalescence from acute diseases of individuals not past middle life, with a fair amount of muscular power and bodily activity. (5) As a prophylactic against hay-fever, cholera, and other infectious diseases. Mountain climates are not advisable in cases of chronic bronchitis, heart-disease, emphysema, Bright's disease, chronic rheumatism, hæmoptysis, nor for aged persons.

**3. Climate of Inland Wooded Districts.**—The climate of wooded districts (elevations above 1,500 feet are not here referred to) is peculiar in several respects. It has a temperature lower than that of the surrounding country—on the average 3° F.—during the hours of daylight; the temperature is also more equable. The relative humidity is higher (9·3 per cent.) in summer than in the less wooded country, and hence there is greater liability to rain and mist. It also affords greater protection and shelter against winds than other climates.

The general effect of woodland climates, as

may be deduced from the above, is sedative and tonic. They may be advised in chronic bronchitis, emphysema, heart-disease, and in hypochondriasis, hysteria, and other nervous affections where tranquillity and subdued light are of importance; also in the earlier stages of convalescence from acute disease when sea or mountain air is too stimulating. In bronchitis pine-woods should be selected, and in heart-cases level walks are essential, unless exercise be deliberately ordered for certain kinds of cardiac disease in the form of graduated hill-climbing.

**4 Ocean Climate: Sea Voyages.**—Voyages have been much recommended in the treatment of phthisis in its early stages, with a view to enable the invalid to spend much time in an exceedingly pure and fairly equable atmosphere, and to secure a sufficient amount of bodily movement without great fatigue.

The drawbacks to the sea ought to be provided against as far as possible, although certain of them from their very nature must be endured. The principal of them are the impossibility of escape from bad weather, and the confinement, perhaps, to ill-ventilated cabins, when such occurs; the absence of sufficient light and air below decks, the latter being felt very much at night; want of variety in the diet after a certain time, and in many instances of fresh food, milk, &c.; monotony in society and occupations; and, lastly, the inconveniences arising from crowding of the main-deck with hen-coops, sheep-pens, &c., and in steamers from the smoke of the engines, and the smell and vibration of the machinery.

The routes generally recommended to invalids are chiefly: (1) to Australia, 90 days in a sailing vessel, 45 in a steamer; (2) to the Cape of Good Hope, 20 days; (3) to the West Indies, 17 days; and (4) to the United States or Canada (in summer), 6 to 7 days. Short cruises in the Mediterranean, or to the latitudes of the Canaries and Azores, are suitable for certain cases where expense is no object. Of routes (3) and (4) we may say that they are too short for the full benefit of the sea to be obtained, as improvement does not generally begin for a week or two after sea-sickness has subsided, and the patient can remain comfortably on deck. Route (2) does not allow him to get the bracing effect of high South latitudes. Hence where a long sea voyage is indicated, route (1) is decidedly the best. England is quitted in the beginning of October, Australia (Sydney or Melbourne), or New Zealand (Wellington), is reached early in January, and the return voyage is begun not later than the end of February.

Patients should not remain in the coast-towns of Australia in summer on account of the heat and the dust. They should go to the table-land of New South Wales, or to the Darling Downs in Queensland, or else they

should cruise from port to port, or cross to New Zealand or Tasmania.

In returning, the route round Cape Horn should be *avoided*, on account of the great risk of the climate of the South Pacific Ocean, and the chance of encountering icebergs, fogs, and unfavourable winds. Either the patient should come back round the Cape of Good Hope; or, if his strength permit, he may cross to California, travel overland to New York and thence by steamer; or, lastly, he may come by the Red Sea, Suez Canal, and Mediterranean.

The invalid must expect about 20 wet days on the voyage out. The temperatures met with range from 40° to 80° F., the coldest and most uncertain weather occurring in the North Atlantic and South Pacific Oceans.

*Choice of Vessel.*—The following considerations may be useful in deciding between steam and sailing vessels:—

For a steamer there is the greater certainty in predicting the length of the voyage, and the calms of the tropics are sooner passed.

Against steamers there is the nuisance of steam and smoke on deck; much space is taken up by the engines, stokers' rooms, &c., and hence other parts of the ship are more crowded; the bilge water is tainted with the engine grease; there is the wearying grind of the screw by day and by night; while more seas are shipped, because a steamer can run against a head-wind.

For sailing vessels there are the advantages of more room, light, and air in the cabins, and the absence of the above-mentioned disagreeable conditions.

Against them there is the longer and more uncertain duration of the voyage, the necessity of shaping their course by the prevailing winds, and the possibility by route No. 1 of being becalmed at the equator for days or weeks, in a humid atmosphere of 80°–85° F.

The vessel selected should not be under 1,000 tons, and her age, class of passengers, the character, temper, and standing of her captain, as well as the reputation of the owners, and the size of her cabins, should be carefully ascertained. Of course it is a *sine qua non* that she should carry a duly qualified surgeon.

The cabin for the outward voyage to Australia should be on the port side, so as to get the breeze in hot weather, and *vice versa* in returning.

The cabin outfit should include a spring mattress, with hair (not wool) mattress over, a folding easy chair, chest of drawers, carpet, curtains, and sponge bath (Faber). Clothes of various degrees of thickness are essential, both for body and head, and a waterproof suit is necessary for bad weather.

Plenty of linen must be taken, as washing is difficult on board, and there should be a supply of preserved milk, meat or essence of meat, fruit, and light wines.

The *indications* for a sea voyage are hereditary tendency to phthisis, or the presence of actual but uncomplicated disease in a very early stage, in persons not past middle life, with a fair digestion, absence of severe pyrexia, and general health not much impaired. Patients with a tendency to hæmoptysis should not be sent, nor should those of a desponding disposition, who would thus be likely to suffer by the long absence from home, or from fears of their personal safety. Of course a tendency to protracted sea-sickness is a distinct contra-indication.

The invalid should be careful not to overtax his digestion too much; he should take regular daily exercise on deck to the extent of his strength, have some definite occupation to beguile the time, and, if possible, be accompanied by a personal friend (Faber).

*Choice of a Climate—General Hints.*—It is a good plan, if possible, to order a patient a climate with that mean temperature and relative humidity which he is known to tolerate well (Sigmund). The patient's disposition must be considered, and a lively or a quiet place chosen according to his temperament. We should not send a poor man to a place beyond his means, otherwise he has to grudge himself many comforts, and loses much, if not all, the benefit of the change. In sending patients to the South of Europe this rule is too often neglected.

The special indications for the climates of particular places can only be understood by studying their local aspect. Generally speaking, as far as Great Britain is concerned, the climate of the east coast is colder and drier than that of the west and south coasts. In Europe the north and west coasts are moister and cooler than the shores of the Mediterranean. As to season, mountain climates include some very important winter stations; woodland climates are almost exclusively indicated from May to the middle of July. Certain parts of the sea-coast are adapted for invalids at all seasons of the year; but as a rule the northern coasts of Europe and the eastern or south-eastern coasts of Great Britain are best suited for summer, and the south, west, and south-western for winter residence. The Mediterranean coast is only to be recommended from mid-October to the middle or end of May, and Egypt should be quitted not later than April. A word may be added as to the advantages of wintering in the South of Europe. It is incontestable that the invalid gets a milder winter, a longer autumn, and an earlier spring. Although there is no place where some days of bad weather do not occur, or where uninterrupted calms are met with, yet the number of rainy days is fewer, there is more sun, little or no fog, and, except in the neighbourhood of the Pyrenees, little or no snow or ice. The scenery is picturesque and attractive, and the invalid is able to spend much time in the open air, and to sit out of

doors on many days, even in mid-winter. The drawbacks to the South are the risk of chills, owing to the difference between sun and shade temperatures, especially at first, when persons are unaccustomed to the climate, and fail to take sufficient care; the occasional occurrence of high winds, especially in spring; the more limited accommodation, owing to the expense of rooms and living; and the absence of many so-called 'home comforts.'

Those who visit the South must remember that the curative value of the climate consists in its *allowing much time to be spent in the open air*, and in its milder temperature and drier air, which protect the respiratory organs from fresh inflammatory attacks. A south room and warm clothing of the texture usually worn in England in autumn are essential, and a coat or wrap should always be carried out of doors in mid-winter to put on in passing from sun to shade. The invalid should strictly avoid the hot atmosphere of gaslit salons at night.

Patients with acute diseases of the respiratory organs should not be sent to the South; and high fever, excessive weakness, or the necessity of remaining in bed, are also contra-indications, owing to the fatigue and risks of the journey and the need of home comforts. Cases of mental disease with excitement, where rest and protection of the mind and body are of primary importance, should likewise not be sent.

In the convalescence from acute diseases occurring in autumn, where a cold northern winter would prevent open-air exercise, and probably set up fresh exacerbations, southern winter climates are of great value.

In ordering change of climate the accommodation, food and water supply, soil and drainage of the locality chosen, should be carefully considered, especially if the distance be a long one. The best climate may be unavailable for the invalid, owing to defects in one or more of these particulars.

Lastly, the patient's own feelings should be carefully consulted before he is sent far away from home. In some cases all the benefits of climate are counteracted by 'homesickness.' *Cælum non animum mutant qui trans mare currunt.*

**Enumeration of Climates.**—We shall now enumerate various climates and regions suitable for the treatment of cases that can be thus benefited.

**1. Of the Nervous System.**—In neuralgia:—Arcachon (for the calm, sedative, yet tonic atmosphere of the pine-woods), Cannes (the districts away from the sea), Upper Egypt (Cairo, Luxor, Helwan), Hastings, Hyères, the Engadine, the Bernese Oberland, Pau, Pisa, Rome, the Salzkammergut (Ischl, Aussee, Berchtesgaden). Some of the above climates will also be found suitable to cases of hemicrania and sciatica.

In hysteria, hypochondriasis, spinal irritation, and in some cases of protracted chorea:—Cannes, Ischl, Aussee, Meran, Mentone, Montpellier, Morocco (Tangiers), Nice, Naples, the Bernese Oberland (Gründelwald, Müren), Palermo, Pau, Seville, Spezia, and Valencia; the effect produced being chiefly due to diversion of the attention by the change of scene, although the bracing influence exerted on the system at large must be taken into account.

In chronic softening of the brain and spinal cord, in paralysis of cerebral origin, and in some cases of locomotor ataxy, the South of France may be advantageously ordered in winter, and Alpine climates of moderate height in summer. As a rule hot climates, or those where the sun has considerable power, are contra-indicated where there is a tendency to apoplexy or hyperæmia of the brain.

Temperate and bracing climates are, as a rule, to be recommended in nervous diseases, to restore the general tone of the system.

The immediate neighbourhood of the sea not infrequently causes nervous excitement, neuralgia, and sleeplessness.

**2. Of the Respiratory and Circulatory Systems.**—In chronic bronchitis, emphysema, bronchial and spasmodic asthma, as well as in chronic pharyngeal and laryngeal catarrh and laryngeal ulceration, the following climates may be recommended:—Africa (South), Algiers, Australia, the Azores, Bordighera, Bournemouth, the Canaries, Upper Egypt, Glengariff, Hastings, Hyères, Lisbon, Madeira, Malaga, Mentone, Meran, Montreux, Nervi, Nice, Palermo, Pau, Penzance, Pisa, Queenstown, Rome, San Remo, Santa Barbara, St. Leonards, Torquay, and Ventnor.

Change of climate is of great value in convalescence from the acute, and as a prophylactic and curative measure in the chronic forms of bronchitis; but we must remember that where there is copious expectoration a dry climate is indicated, while in the irritative forms with scanty sputa (*bronchitis sicca*) a moderately moist mild climate is generally suitable. In emphysema we should choose a mild and not too dry climate, if possible in the neighbourhood of pine-woods, such as Arcachon on the west coast of France, or Bournemouth. In spasmodic asthma the choice of climate must be partly a matter of personal experience.

In the early active, and in the quiescent forms of the later stages of phthisis, as well as in chronic pleurisy, and in convalescence from pneumonia, the following (chiefly winter) health resorts and climates have been favourably spoken of, and many of them will be found described in this work under their own or associated headings:—Africa (South), Algiers; Australia, Bordighera, Bournemouth, Canaries, Cannes, Colorado Springs, Denver, Davos, Upper Egypt, Upper Engadine, South

of France, Falmouth, Hastings, Hyères, Queenstown, Ischl (in summer), Madeira, Malaga, Mentone, Natal, Nervi, Nice, the Oberland (in summer), Palermo, Pau, Pisa, St. Paul's in Minnesota, San Remo, Santa Fé, Sicily, Spezia, Torquay, and the Undercliff (Isle of Wight).

In chronic endocarditis, pericarditis, and in heart-disease generally, a rather bracing climate, without extremes and of the character suited to chronic bronchitis, is usually indicated. Here both the tonic effects of climatic change, and the prevention of pulmonary complications, and fresh rheumatic attacks, must be taken into account. Mountain resorts of moderate height, well-protected from sudden changes of temperature, may be prescribed in summer.

In the neuroses of the heart, including (1) angina pectoris, (2) palpitation associated with chlorosis, hysteria, or hypochondriasis, and (3) exophthalmic goitre, moderately bracing climates are indicated. In angina pectoris long journeys involving fatigue or exertion must be rigorously forbidden, as must also sightseeing or exciting amusements.

**3. Of the Abdominal Organs.**—In the various forms of chronic dyspepsia and intestinal catarrh, in chronic hepatic disease, in chronic dysentery (after removal from a malarial district or tropical climate), in diabetes, and in chronic endometritis, pelvic cellulitis, and other diseases of the uterus and its surroundings, the following climates may be selected from:—Cannes, the Engadine, Hastings, Hyères, Lisbon, Malta, Mentone, Montpellier, Morocco, Naples, Nice, the Nile, the Bernese Oberland, Pontresina, the Pyrenees (in summer), Queenstown, Schwalbach, Seville, Spezia, St. Moritz, Valencia, and Ventnor.

In convalescence from acute nephritis, and in all forms of chronic Bright's disease, but especially *catarrhal* nephritis, warm dry climates are indicated. Among the best are Upper Egypt, the Riviera, the Cape of Good Hope (inland), Bombay; and, in England, Brighton, Folkestone, Hastings, and Ventnor.

In renal calculus, removal from particular districts in which stone is known to be prevalent may possibly be of use in some cases.

**4. Of the System at large.**—Change of climate is here nearly always indicated:—

(1) In convalescence from typhus and typhoid fevers, scarlet fever (at the end of the desquamative stage), measles, diphtheria, and acute rheumatism; also in the third stage of protracted whooping-cough.

(2) As a prophylactic against all infectious diseases, and especially cholera, yellow fever, hay fever, influenza, and malaria; also against rheumatism and phthisis by withdrawal from damp districts, and goitre and cretinism by removal from the *ensemble* of conditions to which the latter are due.

(3) In rickets, scrofula, chlorosis, general

anæmia, and functional debility. Here, where a pure air and a bracing sunny atmosphere are the chief indications, the climates enumerated in section 1 are suitable; as are also Algiers, Biarritz (in autumn), the Cape of Good Hope, Ischl, Malaga, Rome, Sicily, St. Moritz; and, in Great Britain, a number of inland and seaside places (Malvern, Scarborough, &c.) which it is unnecessary to mention.

EDWARD I. SPARKS. M. CHARTERIS.

**CLINICAL** (κλίνη, a bed).—This word literally signifies 'of or belonging to a bed'; but it has been especially applied to the practical study and teaching of disease at the bedside; and has more recently been extended to all that relates to the practical study of disease in the living subject generally.

**CLONIC** (κλονος, tumultuous movement). This word is applied to spasmodic movements which are of short duration, and alternate with periods of relaxation. See CONVULSIONS; and SPASM.

**CLONUS** (κλονος, tumultuous movement). The term now applied to the movement of a portion of a limb by striking or forcibly stretching one of its tendons. See SPINAL CORD, Diseases of; § 5. SPINAL REFLEXES.

**CLOT.**—A clot, or coagulum, is the product of the formation of fibrin (see BLOOD, Morbid Conditions of). Coagulation of the blood within the blood-vessels is described under THROMBOSIS; the coagulation of extravasated blood under HÆMORRHAGE, and BRAIN, Hæmorrhage into; and the coagulation of inflammatory exudations under INFLAMMATION.

**CLOTHING.**—See DISEASE, Causes of; and HEALTH, Personal.

**COAGULUM** (*coagulo*, I curdle).—See CLOT.

**COAL GAS, Poisoning by.**—Coal gas, so largely employed for illuminating purposes, is a compound containing—in addition to olefiant gas and analogous hydrocarbons, on which the luminosity principally depends—certain so-called diluents, which burn with a non-luminous flame, namely, hydrogen, marsh-gas, and carbonic oxide, along with what are termed impurities, of which the chief are carbonic acid, sulphuretted hydrogen, and bisulphide of carbon. On these impurities the characteristic odour mainly depends. This odour, which is perceptible even to the extent of 1 in 10,000, is a valuable safeguard against accidents from escape of gas. The recently introduced water gas, made by decomposing aqueous vapour over burning coke, while it is more dangerous—only 1 per cent. being necessary to produce a fatal result—has not even this safeguard, for it is quite odourless.

A mixture of coal gas with the air inhaled exerts a deleterious effect on the system, and proves fatal when it reaches a certain percentage. In addition to the danger from inhalation, fatal accidents frequently occur from the explosive nature of the compound which is formed when the gas reaches the proportion of 1 to 10 of the atmosphere. Much less than this, however (a non-explosive mixture, therefore), proves fatal if long inhaled.

It is difficult to determine the exact proportion of the gas present in atmospheres in which fatal accidents have occurred, but we derive important information on this point from experiments on animals. Many such have been made. M. Tourdes, who has carefully investigated the subject, finds that pure gas is almost instantaneously fatal;  $\frac{1}{4}$ th kills rabbits in five minutes, and dogs in twelve minutes;  $\frac{1}{3}$ th kills rabbits in from ten to fifteen minutes;  $\frac{1}{6}$ th still proves fatal after a longer period; and evident signs of distress are caused in rabbits by an atmosphere containing only  $\frac{1}{10}$ th of the gas. Dr. Taylor (*Edin. Med. Journ.*, July 1874) has estimated the proportion of gas existing in a room in which a fatal case occurred at three per cent.

**SOURCES OF POISONING.**—Poisoning by coal gas is only known of as an accident. Occasionally suddenly fatal consequences ensue among workmen from exposure to a sudden rush of undiluted gas from gasometers and mains. More commonly slowly fatal cases result from the gas tap in a bedroom being left open carelessly, from accidental extinction of the light, or from leakage of gas-pipes in a house or at a distance. The gas gains access to the house in the latter case through cellars, walls, and more especially by means of drains and sewer-pipes, most commonly during winter and severe frosts, presumably from the ground surface being frozen and preventing escape into the streets. After passing underground, coal gas loses its odour, which is such a safeguard, most of the carburetted hydrogen and marsh gas is absorbed, and the amount of carbonic oxide is increased.

**SYMPTOMS.**—Gas, even when in comparatively small proportion and just sufficient to cause an unpleasant odour, acts deleteriously if long breathed, and gives rise to headache and general depression of health. A very slight escape of coal gas—just sufficient to produce a close smell, not like that of gas, and therefore not recognisable as such—will cause relaxed or ulcerated throat, probably from the irritation of the sulphur compounds.

In severe and fatal cases the symptoms which have been noted are headache; nausea or vomiting; vertigo; and loss of consciousness, passing into deep coma and muscular prostration, which resembles the apoplectic state, the individual lying insensible and incapable of being roused, with livid features, stertorous breathing, and froth at the mouth.

Death usually occurs quietly, in this state of coma, but occasionally with convulsions.

The state of the pupils does not seem to be constant, though they are generally dilated before death.

In Dr. Taylor's case (*sup. cit.*) the teeth were firmly clenched, and the eyes were in a constant state of lateral oscillation.

**FATAL PERIOD.**—The fatal period of poisoning by coal gas is extremely variable, and a remittent character of the symptoms sometimes gives rise to fallacious hopes of recovery in cases which ultimately prove fatal.

**DIAGNOSIS.**—The smell of gas in the clothes, breath, and perspiration, which continues for a considerable time after removal from the polluted atmosphere, is the best indication of the cause of the coma.

**ANATOMICAL CHARACTERS.**—The smell of gas is often very marked. M. Tourdes found the blood as a rule dark, but in some recent cases it has been noted as being of a bright red colour. Other signs are: a bright coloration of the pulmonary tissue; froth in the air-passages; congestion of the mucous membrane at the base of the tongue, the mucous membrane of the trachea being in some cases a bright rose colour; engorgement of the cerebral and spinal venous system; and rose-coloured patches on the thighs.

**MODE OF ACTION.**—It is obviously impossible to differentiate between the effects of the various constituents of coal gas, but we have good reason for believing that the most active agent is the carbonic oxide, which exists in the proportion of from five per cent. (English gas) to twenty-five per cent. The active agent is the same in water gas, which contains forty-four per cent. of carbonic oxide.

The symptoms in the main agree with those caused by carbonic oxide (*see* CARBONIC OXIDE, Poisoning by), and the effects, therefore, would be chiefly due to the action of the carbonic oxide on hæmoglobin. The blood of one patient after sixty hours gave the spectrum of CO-hæmoglobin, and Grehaut calculates that 100 c.c. of blood from an animal poisoned with gas give 20 c.c. of CO.

**TREATMENT.**—Instant removal from the polluted atmosphere is the first thing to be attended to. Attempts must then be made to cause oxygenation of the blood, by artificial respiration and excitation of the respiratory centres, by reflex stimulation of the face, chest, &c. Pure oxygen gas may be administered. As, however, the compound which carbonic oxide makes with the blood colouring-matter is a very stable one, and not easily broken up by the introduction of atmospheric air or oxygen, it not infrequently happens that these measures prove of no avail. In such cases it would be highly advisable to perform venesection, and then transfuse fresh blood, a plan of treatment which has been found successful in poisoning by carbonic oxide.

D. FERRIER.

**COARCTATION** (*coarcto*, I straiten). A pressing together, narrowing, or stricture of any hollow tube, such as the aorta, intestine, or urethra.

**COCYGOODYNIA** (*κόκυξ*, the cuckoo; and *δδύνη*, pain).—**SYNON.**: Fr. *Coccygodynie*; Ger. *Steissbeinschmerz*.

**DESCRIPTION.**—This name has been given to a peculiarly severe and obstinate neuralgic pain in the neighbourhood of the coccyx, incited by such actions as defæcation, walking, sitting down, or rising from a recumbent position. It may arise from injury, such as fracture or luxation or horse exercise; or it may be the result of inflammatory affections of the sacro-coccygeal joint or of the pericoecygeal fibrous structures. Coccygodinia is also a concomitant symptom of many rectal, vulval, vaginal, and uterine disorders, being excited whenever any of the muscles which have their insertion in or near to the coccyx are brought into play. It not infrequently is a sequela to a difficult instrumental parturition, or may be a neurosal condition associated with gout or rheumatism.

**TREATMENT.**—In cases where the affection is primary, recourse must be had to rest in the lateral posture, anodyne suppositories of extract of belladonna and opium, and to the careful regulation of the bowels. If the pain be very severe, a local hypodermic injection of morphine may have to be administered. To be successful in our treatment we must, however, always endeavour to differentiate by means of a carefully conducted systematic examination the cause or causes which may be at work, and to attend to the proper indications. Tenotomy and excision of the coccyx have not proved to be uniformly successful, and should therefore only be had recourse to in specially selected cases. Attention must be paid particularly to the nervous system, and the general nutritive processes improved by the administration of arsenic, quinine, and iron.

JOHN HAROLD.

**COLD, A.**—A popular name for Catarrh. See CATARRH.

**COLD, Ætiology of.**—See DISEASE, Causes of.

**COLD, Effects of Severe or Extreme.**—**INTRODUCTORY.**—The general effect of exposure to severe or extreme cold is to lower, even to extinction, all vital activity. The blood-vessels, especially the smaller arteries and capillaries, after a brief period of congestion, become contracted, the latter to such an extent as no longer to permit the passage of the red corpuscles; the normal condition, composition, and structural integrity of the various tissues are more or less impaired, or altogether destroyed; the red corpuscles become first crenated and later disorganised and broken up, the watery elements of the blood thicken, and when

frozen become more or less separated from the saline and other constituents; and those processes of chemical and physiological change which are essential to every manifestation of life, being only possible within certain very narrow limits of temperature, are hindered or absolutely prevented.

The more *special effects* vary in degree and kind:—1st, with the degree of cold, the duration of the exposure, and the medium or manner of application; 2nd, with the part, and extent of surface exposed; and, 3rd, with the general constitution and physiological condition of the sufferer.

Moderate cold, acting during a short time, or even severe cold during a still shorter time, followed by the glow of speedy reaction, exercises a tonic and stimulating influence. If, however, the cold is very severe, or the exposure too long, the glow of reaction does not occur, but a sense of depression is experienced, from which, at best, recovery takes place but slowly. Continued exposure to such a degree of cold as is yet not incompatible with the maintenance of life, nevertheless keeps at low ebb activity of nutrition and function alike. Extreme cold and long exposure lead to congelation and consolidation of the various tissues of the body. After complete congelation of the body recovery is impossible.

Dry cold is much less readily injurious in its influence than cold associated with wet. The better conductor of heat the medium is, the more speedily and completely does it reduce the temperature of the part with which it is in contact. Immersion in water cools more rapidly than exposure to air of the same temperature; and contact with wool, wood, or metal, of the same degree of coldness, excites in each case a different sensation, and leads to a different result, or to similar result but with very different rapidity. Constant renewal of the medium in contact hastens the cooling effect; and a continuous draught of only moderately cold air may do more to chill than temporary exposure to an intensely cold but still atmosphere. If some external part, and a comparatively small extent of surface only, be acted upon, the effect may be simply local, and the general disturbance of the system scarcely appreciable. But if the whole body, or a considerable extent of surface, or any important internal organs be acted upon, a proportionately serious general effect is produced.

The young (infants especially) and the aged alike ill sustain exposure to cold, and are most liable to suffer, not only from its direct effects, but also from the various maladies to which it gives rise. The feeble, ill-nourished, and broken in health, especially the subjects of organic disease, or of degeneration due to habitual intemperance, readily succumb, or only slowly and imperfectly recover. Among the healthy and otherwise vigorous, hunger, fatigue, sleep, anxiety of mind, fear, and

mental depression of whatever kind, lower—too often even to fatal issue—the power of resistance to the deadly influence of cold.

**LOCAL EFFECTS.**—For local effects of exposure to cold, see CHILBLAIN; FROST-BITE; and GANGRENE.

**GENERAL EFFECTS.**—The general effects and symptoms produced by exposure to severe or extreme cold vary in different cases. Temporary exposure produces, first, a sense of coldness or chilliness, associated with paleness and corrugation of the skin (the so-called *cutis anserina*), then shivering and tingling sensations, followed by numbness and diminution of muscular activity and power. Healthy reaction restores more or less quickly the normal condition. Prolonged exposure to extreme cold gives rise to a series of symptoms, graphically described by Beaupré somewhat as follows:—Reaction has a limit, and a moment arrives when the powers are exhausted. Shiverings, puckerings, paleness and coldness of the skin, livid spots, muscular flutterings, are symptoms of the shock given to the vital forces; syncope approaches; the stiff muscles contract irregularly; the body bends and shrinks; the limbs are half-bent; lassitude and languor invite to repose; a feeling of weight and numbness retards the steps; the knees bend; the sufferer sinks down or falls; the propensity to sleep becomes irresistible; everything grows strange; the senses are confused; the mind grows dull, the ideas incoherent, and the speech stammering or raving; respiration, at first interrupted, becomes slow; the heart's action is feeble, quick, hard, irregular, and sometimes painful, and the pulse progressively smaller; the pupils dilate; the brain becomes stupefied; and finally deep coma indicates the approach of inevitable death.

Other and somewhat different effects and symptoms, attributable to differences of circumstances and condition, have been from time to time observed. Distressing and almost intolerable thirst, with loss of appetite for food, is often experienced; and the attempt to obtain relief, by sucking snow or ice, only adds to the suffering. Somnolence is by no means so constant an effect as is commonly supposed—at any rate, in the earlier stages, and less extreme cases. On the other hand, inability to sleep has proved a common cause of suffering and consequent loss of strength. The manifestations of brain-disturbance due to exposure to cold, varying as they do from dulness, incoherence, wandering, and thickness of speech, to even raving delirium, are especially worthy of note, inasmuch as they resemble, and are liable to be mistaken for, the effects of alcoholic intoxication.

Death from the direct and immediate effects of cold is rare in the British Islands; but it is estimated that in the Russian Empire, on an average, 694 deaths occur annually

from this cause. The length of time during which exposure can be sustained varies greatly with the condition of the individual and with surrounding circumstances, as well as with the degree of cold. Under ordinary circumstances, an hour's exposure to intense cold, without due protection against the loss of natural heat, often suffices to determine a fatal result. At the same time, well-authenticated cases are on record, in which persons buried, for days even, in snow, have nevertheless survived and ultimately recovered with little permanent damage.

**MODE OF DEATH.**—The immediate cause or mode of death occurring directly from exposure to cold seems in some cases to be principally shock; in some, syncope; in some, apoplexy; in others, asphyxia; and in others, again, coma. In most cases it is probable that these several conditions, with others less readily specified, combine to produce the fatal result.

**ANATOMICAL CHARACTERS.**—The appearances presented on *post-mortem* examination are somewhat differently described and estimated by different observers; but none of them are absolutely pathognomonic, and some are as likely to be produced by exposure of the body after death as during the process of extinction of life. Among the more noteworthy are the following:—strong cadaveric rigidity; paleness or waxy whiteness of skin, with patches of more or less bright redness about the face, neck, and limbs, especially on exposed or prominent parts; a contracted and shrunken condition of the male genital organs; comparative bloodlessness of superficial and external parts; accumulation of blood in and about the thoracic and abdominal viscera; great distension of all the cavities of the heart, with more or less clotted and often bright-coloured blood; the blood in other parts also sometimes of brighter colour than usually seen on *post-mortem* inspection; hyperæmia and congestion of the lungs; hyperæmia of the brain, overfulness of the sinuses, and excess of serous fluid in the ventricles, and at the base, in some cases; in others, comparative bloodlessness of the surface of the brain, and no distension of the sinuses; excessive fulness of the urinary bladder; and, lastly, separation of the cranial bones along the coronal and sagittal sutures. The lines of reddish or brownish staining along the course of the superficial blood-vessels, relied on by some as pathognomonic, are certainly not so, inasmuch as they depend upon exosmosis of the blood colouring-matter set free by disruption of the corpuscles, which may be effected by freezing after death, as well as before.

**TREATMENT.**—The treatment of sufferers from the effects of cold consists in the restoration of warmth, and the rekindling of those processes by which the natural heat of the body is maintained. But this must be done

gradually, and with great care. As in the treatment of a frost-bitten part, so in the treatment of the body generally—all sudden or rapid elevation of temperature must be avoided. The sufferer, divested of the clothing previously worn, and wrapped in blankets, should be placed in the recumbent position in a room, the air of which is dry, still, and cold, but capable of being gradually warmed. Gentle but continuous friction should be made over the trunk and limbs, care being taken that rigid or frozen parts be not damaged by rough manipulation. At first, ice or ice-cold water may be used; afterwards dry rubbing with flannel or with the hands is better; later still some stimulating liniment may be employed. Some recommend immersion of the body in a bath of cold—at first ice-cold—water, the temperature of which can be gradually raised. This method would seem easy and advantageous, if means are at command. When the sufferer can swallow, warm, gently stimulating drinks—as tea, coffee, aromatic infusions, beef-tea, or soup—may be given, at first without, but later with some wine or spirit. Alcohol, though useless or injurious if taken to fortify against cold, is useful and beneficial when judiciously administered as a restorative after exposure. In all cases of insensibility, and even apparent death from cold, every effort must be made to restore animation; and the attempt must be persevered in for a considerable time before being given up as hopeless. It is often difficult, sometimes impossible, to judge whether life is absolutely extinct or not. And while, on the one hand, it is important that the temperature be not raised too quickly, lest reaction should be too strong or dangerously irregular; on the other hand, it is equally if not more important that the needful measures be adopted without delay, and carried out not too slowly, lest the chance of revival should be lost. In the less severe cases, restoration of warmth may be comparatively quickly accomplished. The state of the bladder should always be examined, and relief afforded, if needful, by aid of the catheter. Attention to the general health is often requisite for long after recovery from the more immediate effects of exposure has taken place. Rest, good nourishment, and tonics are indicated.

**Cold as a Cause of Disease.**—As a predisposing and exciting cause of disease, cold proves, in the British Islands, year by year, more fatal in its effects probably than any other single condition or influence. Any considerable fall in the thermometer below the average standard during the colder months of the year is constantly followed by a corresponding rise in the death-rate, and an increase in still greater proportion in the amount and extent of sickness and suffering. The Reports of the Registrar-General clearly prove this, so far as the death-rate is concerned. A

striking instance may be quoted. In the week ending December 19, 1863, in the London district, 1,291 deaths were registered. Severe frost set in, and in the week ending January 9, 1864, the number rose to 1,798. The week following, ending January 16, no fewer than 2,427 deaths were registered. This enormous increase could be attributed to no other cause than the effects of the severe cold which prevailed. The Registrar-General also shows that after the age of from twenty to forty the mortality from cold increases in something like a definite ratio with increasing years.

General depression of the vital powers, congestion and functional derangement of various internal organs—the lungs, liver, and kidneys—catarrhal and other forms of inflammation of the mucous membranes, especially of the respiratory tract, but also of the intestinal canal and bladder, paralysis from central or peripheral lesion, together with rheumatism, chilblain, frost-bite, and gangrene, constitute the list of maladies most commonly caused and fostered by exposure to the influence of cold.

ARTHUR E. DURHAM.

**COLD, Therapeutics of.**—The therapeutic uses of cold are various and extensive. Cold may be applied as moist cold, by means of wet compresses and cold lotions or baths; and it may also be used as dry cold in the form of ice enclosed in a receptacle of metal or india-rubber, or as a current of iced water circulating through a soft metal coil, as in Leiter's tubes. The flat coil of tube can be pressed to fit any part of the body. Each of these methods has its special advantages and adaptations. Furthermore, cold may be made use of by the mouth, and by injection into the mucous canals of the body.

**GENERAL PRINCIPLES.**—The general effects of cold, however applied, are to lower temperature, to diminish sensibility and fluidity, to contract the tissues and vessels, and so to reduce the volume of parts. The cold bath and cold sponging alike have the effect of lowering the temperature of the body. The fall of temperature sometimes is but transient, reaction setting in and heat of surface returning when the body is withdrawn from the cooling medium. At other times the temperature continues to fall after the individual is removed from the bath. If the action of the cold bath be prolonged, then a thermometer, introduced within the rectum, shows a great depression of temperature, and much pain is experienced, similar to the severe pain which is felt in the hand and arm when the former is held for some time in water at a temperature of 41° F., and which soon compels the withdrawal of the hand from the vessel. Cold baths and their uses are treated of in another article (*see BATHS*), but attention may here be drawn to

the practice of cold sponging over the surface as an efficacious means of lowering preternatural heat and relieving acridity and dryness of the skin during fever. The addition of enough solution of potassium permanganate to give a slight purple tinge to the water, makes it especially refreshing to the patient. Reduction of hyperpyrexia by means of cold is now a well-established therapeutic method. See FEVER; and TEMPERATURE.

**METHODS OF APPLICATION AND USES.**—There are several methods of applying cold therapeutically:—

**1. Cold Affusion and Wet Packing.** In the practice of cold affusion, introduced by Dr. Currie, in 1797, the patient is unclothed, seated in a tub, and four or five gallons of cold water thrown over him. Thus, Dr. Currie said, a commencing fever might be 'extinguished.' In cases where the skin was burning hot and dry, it was observed that after the cold affusion temperature fell, perspiration broke out, and the patient usually dropped into a refreshing sleep. If the body-heat did not exceed 98.4° F., or if the patient was damp and chilly, with or without delirium, the cold affusion was regarded as dangerous and by all means to be avoided. Drs. Strauss and Hirtz speak most highly of the marvellous effect of cold affusion in cases of collapse during fever. This kind of collapse appears due to a paralysis of the nervous centres: the heart's action fails, as does also the respiration; but while the surface of the body is cold, the temperature, taken in the rectum, still remains abnormally high. The affusion is applied by pouring a pitcherful of water, at a temperature of, or a little above, 10° C. (50° F.), over the patient seated in a bath or on a waterproof cloth. The patient, plunged in stupor, is suddenly roused by the shock; he draws a long breath; the respiration becomes fuller; the cardiac ataxy ceases, and the pulse, which, traced by the sphygmograph during the collapse, presented a scarcely broken horizontal line, now regains its normal line of ascension; heat of surface returns, and the temperature in the rectum falls. The action of the cold affusion, as thus applied, is to excite immediate and energetic reflex action.

In many nervous affections, such as maniacal delirium, chorea, and hysteria, cold douches, shower baths, and affusions are valuable as restorative and curative agents. In the convulsions of robust children, a stream of cold water directed over the head from a height of two or three feet often has a speedily beneficial effect. Cold affusion has been tried in tetanus, but it has in some instances killed the patient (Elliotson).

Other cases in which cold affusions are of service are those where respiration fails, and it is necessary to appeal powerfully to the reflex excitability of the nervous centres. To resuscitate those who are in danger of death

from a narcotic such as chloroform or opium, slapping the patient severely with a cold wet towel is an efficient method. In sunstroke, cold affusion over the head and neck may be resorted to, provided the skin be not cold and clammy, and the patient in a synopal state. In conditions of nervous spasm—of the larynx, for example—cold douches over the neck may prove useful. Cold affusion to the feet was much commended by Cullen as a means of promoting action of the bowels in cases of obstinate constipation. Spasmodic retention of urine has been relieved by a cold douche over the perineum and thighs (Currie); and Mr. Erichsen mentions the case of an old man who found his power of micturition increased by sitting on the cold marble top of his commode. In cases of extreme debility, with damp, cool skin, low muttering delirium, and very feeble pulse, cold affusions are dangerous.

In some cases of fever, where for any cause a cold bath is objectionable, the patient may be wrapped in a wet sheet and then covered with a few blankets. The sheet as it becomes heated may be changed for one fresh and cold, or very cold water may be squeezed from a sponge over the sheet as the patient lies rolled up in it on a waterproof cloth. Allowing fragments of ice slowly to melt on the sheet which covers the patient is, in the author's experience, a successful way of treating the hyperpyrexia of acute rheumatism. In scarlet fever of malignant type, where the rash does not readily appear, this form of cooling pack has been found most valuable. The late Dr. Hillier and Dr. Gee have both added their testimony to its utility. In Dr. Gee's cases the patient remained packed in the wet sheet for one hour and was then removed to bed. The cases best suited for treatment by the wet pack are those where the skin is very dry and hot, and the patient exceedingly restless and delirious.

**2. Cold Compresses, Ice-Bags, Irrigations, Lotions, and Injections.**—Cold may be continuously applied with a view to abating undue heat of a part of the body. Iced-water rags or compresses may be placed over an inflamed throat, or on the head in inflammation of the brain. A narrow bladder of ice laid over each carotid artery in the neck is an excellent way of cooling the blood as it flows to the brain. In acute pneumonia Niemeyer has commended strongly the use of cloths dipped in cold water, well wrung, and then applied so as to cover the chest, and especially the affected side. These compresses are repeated every five minutes. Pain and dyspnoea are much relieved; sometimes the temperature falls an entire degree; and if the cold appliances do not arrest the actual attack of pneumonia, they may shorten its duration and promote convalescence. The necessity of so often having to change the compress, and thus disturb the patient,

is a great objection to this mode of applying cold. Dr. Lees, in the *Lancet*, Nov. 2, 1889, records several instances of arrest of the pyrexial process in pneumonia by means of a bag of ice applied over the inflamed lung. The development of broncho-pneumonia in children may be cut short by the ice-bag. A frozen compress over the cæcum is useful to stay peristalsis and check hæmorrhage in typhoid fever.

A powerful sedative and antiphlogistic effect of cold can be obtained by *irrigation*; i.e. allowing cold water to fall drop by drop on a cloth, so as to keep it continually wet with fresh supplies of water. This may be done by suspending over the part to be irrigated a bottle of water, in which a few pieces of ice may be put; one end of a skein of cotton, well wetted, is then allowed to hang in the water, while the other end is brought over the side of the bottle. This, acting as a syphon, causes a continual dropping upon the part to be irrigated. In injuries of joints, where it is of much consequence to check inflammation, this process, which abstracts heat gradually and without disturbance of the part, is most valuable. Irrigation of the shaven scalp in cases of meningitis is a very powerful cooling and sedative appliance, requiring care and watchfulness. A cap of india-rubber or coil of tubing over the head and back of neck, so arranged that a current of cooled water may flow continuously through it, will act as a general reducer of temperature. Where pounded ice is applied to the head in a bladder, this should be suspended by a string from the bedstead, so that the head of the patient may not have to sustain the weight of the bag and its contents. Five ounces of sal ammoniac and five ounces of nitre in a pint of water will form a frigorific mixture, which can be applied in a bladder when ice is not at hand. The ice-bag, and cold-water compresses renewed every three minutes, have been used as an appliance to strangulated hernia, and to prolapsed rectum, to reduce the volume of the part and so facilitate reduction. Care must be taken that the cold application be not continued so long as to cause gangrene. Cold wet compresses should not be applied over dry bandages, with which wounded or broken parts are secured. Several cases are recorded where a hand or arm has become gangrenous, in consequence of having been bound up with dry bandages, and then treated with cold-water compresses. The dry bandages, as they become wet, contract tightly on the limb and stop the circulation.

A mixture made of spirit of wine and water, or of eau de Cologne and water, is a simple form of *cooling lotion*. The spirit evaporates and so carries off heat from the surface. 1 fl. oz. of rectified spirit to 15 of water makes a good spirit lotion, and the addition of 4 drachms of nitrate of potassium, or

chloride of ammonium, will add to its cooling and sedative effect. 4 drachms of the chloride of ammonium with half a fluid ounce of diluted acetic acid, and the same quantity of rectified spirit, in 15 fl. oz. of camphor water, is another form for a very serviceable lotion. These lotions, applied by means of a piece of soft rag or lint over the skin, act as refrigerants, cooling the head when it is hot or painful; reducing heat and arterial excitement in tumours or contusions; and tending in the latter to promote the absorption of effused blood. A lotion of 1 part alcohol and 3 parts camphor water, at a temperature of 75° to 85° F., was highly praised by Scudamore in cases of gout. Cold water, and cold lotions of vinegar and water, are familiar means for stopping hæmorrhage.

In cases of severe uterine hæmorrhage, *injections* of ice-cold water into the vagina, or into the rectum, frequently succeed in checking the bleeding. If the cold injection fail, hot water (110°-120° F.) may be tried in its place. In cases of bleeding internal piles, an injection of cold water, after the action of the bowels, braces the parts and constricts the bleeding vessels. Iced water has been used as antipyretic enemata.

3. *Dry Cold. Uses of Ice.*—Heat may be continuously abstracted from an inflamed part in a safe way, and without undue risk, by applying dry cold by means of a waterproof bag of vulcanised india-rubber filled with ice, snow, or a freezing mixture made of equal parts of salt, nitrate of potassium, and chloride of ammonium. Moisture from the air will condense on the exterior of the cold bag, but a piece of lint interposed will protect the skin from damp. The india-rubber is a bad conductor, and too great abstraction of heat need not be feared. The walls of an animal bladder conduct heat much better than the india-rubber, and it is necessary to watch carefully over the application of ice-bladders, for when continuously applied they have been known to cause severe frost-bite of the part. If, when cold is being applied, the patient persists in complaining of severe pain, it is right to examine carefully and see how the part is affected by the cold. Professor Esmarch, in cases of fracture, and in various forms of traumatic inflammation, has applied ice for periods of twenty or thirty days with the best results. In cases of commencing disease of the vertebræ this surgeon has used cold water placed in a tin vessel, so made as to adapt itself to the part to be treated. Minor cases of bruise with inflammation may be treated by cold employed in the form of a common bottle filled with cold water and kept pressed against the part. After operations upon the eye, the extraction of cataract for example, a small ice-bag is very useful in relieving pain and keeping down inflammation. For the same purpose an ice-

bag is sometimes applied to the chest after the operation of paracentesis.

Ice-bags placed along the course of the spine have been found effectual remedies in many forms of nervous disorder. In cases of epilepsy, where the circulation is sluggish, the hands and feet being always clammy and cold, an india-rubber bag of ice applied along the spine has been found to restore warmth, at the same time relieving headache and symptoms of incipient paralysis. Cold to the spine is asserted by Dr. Chapman to lessen the excito-motor power of the cord. In the severe pain of an inflamed ovary or testicle ice in a bag may often be employed beneficially as an anodyne. The long-continued application of bags of ice to the chest, for the arrest of hæmorrhage from the lungs, has been observed by Sir Richard Quain and others to be very apt to cause bronchitis.

Lumps of ice swallowed are invaluable in arresting hæmorrhage from the throat and stomach. In tonsillitis and diphtheria this same treatment tends to reduce inflammation and cool the throat of the patient. Obstinate vomiting can often be checked by swallowing fragments of ice.

**4. Cold as an Anæsthetic.**—Dr. James Arnott, in 1849, brought forward the use of a freezing mixture of ice and salt as a means of producing local anæsthesia, by freezing the part to which the mixture was applied either in a bag or in a metallic spoon. For small superficial operations this method of anæsthesia by congelation answers very well. The part becomes white and hardened to the cut of the surgeon's knife, there is very little hæmorrhage, and the wound made usually heals well by primary adhesion.

Subsequently Dr. Richardson indicated a very convenient way of inducing local anæsthesia, by the volatilisation of ether in the form of spray, by means of the hand-ball spray atomiser. Ether sprayed on the bulb of a thermometer, held about an inch from the jet, brought down the mercury to within 10° of zero F. When the jet was turned on to the skin, a marked degree of local anæsthesia was produced, but not enough for surgical purposes. By driving over the ether under atmospheric pressure, instead of trusting simply to capillary action—or to suction, as in Siegle's apparatus—one may bring the thermometer to 4° below zero within thirty seconds. By the use of this apparatus, at any season or temperature, the surgeon can produce cold even 6° below zero; and by directing the spray upon a half-inch test-tube containing water, he can produce a column of ice in two minutes. For local anæsthesia by cold, the ether spray answers well. Such operations as the removal of small tumours, opening abscesses, and inserting sutures may be painlessly performed.

JOHN C. THOROWGOOD.

**COLIC** (κόλον, the large intestine).—Originally colic signified a painful affection due to spasm of the bowel, but, though still retaining this application, it has now come to be further associated with other complaints which are attended with severe pain of a spasmodic character, a qualifying adjective indicating the nature and seat of each particular form. Thus *renal colic* is applied to the group of symptoms due to the passage of a stone from the kidney to the bladder; *hepatic colic* to those accompanying the escape of a gall-stone. See COLIC, Intestinal.

**COLIC, INTESTINAL.**—SYNON.: Fr. *Colique*; Ger. *Die Kolik*.

**DEFINITION.**—Painful and irregular contraction of the muscular fibres of the intestines, without fever.

**ÆTIOLOGY.**—*Predisposing causes.*—These include the nervous (as hysteria and hypochondriasis), lymphatic, and bilious temperaments; sedentary occupations; the female sex; and the period of youth or adult age. *Exciting causes.*—These may be grouped as follows:—

1. Irritation—from lodgment of gas due to fermentation of undigested food, and decomposition of feces long retained within the large intestine; from feces, or intestinal concretions, undigested or partly digested food, such as pork, shell-fish, salt meats, unripe fruit, or septic game; from cold drinks or ices; from excessive or morbid secretions, especially bile; from gall-stones; or from worms—a bundle of round-worms or coiled up tape-worms. 2. Morbid states of the bowel, including obstruction from intussusception, twisting, strangulation, &c.; ulceration (typhoid, tubercular, dysenteric); inflammation (enteritis, typhlitis, &c.) 3. Reflex nervous disturbance, due to anxiety, fright, anger, or other emotional disorder; to disease of the ovaries or uterus; to calculus (hepatic or renal); to dentition; or to exposure, especially of the feet and abdomen, to cold. 4. Blood-poisoning, as from lead, copper, gout, rheumatism.

**SYMPTOMS.**—The characteristic or essential symptom of intestinal colic is pain in the abdomen, without febrile disturbance. It usually begins, and is most severe, in the umbilical region, then spreads to other parts, or to the whole abdomen, and is apt to travel from one part to another. It is almost always relieved by firm pressure, and by expulsion of flatus; and is paroxysmal in character, remitting, or exacerbating, or completely subsiding at intervals. The suffering is usually severe, often agonising, and to relieve it the patient bends forwards, pressing the abdomen firmly with his hands or against some hard surface, or rolls about. As a rule the abdomen is distended by flatus; in lead-colic it is, however, firmly retracted towards the spine, and the movements of the inflated intestines affected by spasmodic contraction,

producing loud borborygmi, may frequently be seen and may be felt by the hand applied to the abdomen. The muscles of the abdominal wall and the bladder usually participate in the internal spasm: the abdomen becomes rigid or knotted, and the recti muscles become contracted into round balls, while frequently the navel is retracted; micturition is frequent or suppressed. Usually there is constipation, and the pain disappears when the bowels are freely relieved; sometimes, however, it persists for a time. Constipation stands in a twofold relation to colic, either as cause or as effect of the spasm.

The countenance expresses great suffering, anxiety, and depression, and the features may be pinched. The surface of the body is cold, especially the feet, and the pale skin is covered by a cold perspiration. The pulse is commonly of normal frequency, or is infrequent and feeble.

The symptoms vary somewhat with the cause. When due to irritating ingesta, the prominent symptoms are vomiting and diarrhoea, sometimes ending in catarrhal dysentery. In children the legs are drawn up upon the abdomen; the bowels are often at first confined; and the evacuations are greenish, offensive, and very acid, afterwards becoming loose.

In nervous and hypochondriacal subjects, and especially females, severe pain in the intestines, resembling that of spasmodic colic, is apt to occur (*see* ENTERALGIA). Flatulence plays a varying part in different cases; it is often a prominent symptom, and the form of colic thus characterised has been termed *Colica flatulenta*.

Vomiting is generally in proportion to the severity of spasm and the degree of intestinal obstruction.

**DURATION.**—The duration of the attack varies greatly, from a few minutes to several days. The spasm usually ceases abruptly, leaving a feeling of soreness in the abdomen, while there is enjoyable relief from suffering. Colic, when violent or intractable, may terminate in enteritis, in peritonitis, and—especially with children—in intussusception.

**DIAGNOSIS.**—A pain moving from place to place, relieved by firm pressure and unattended by fever, separates colic from other affections, more particularly from those due to inflammation, in which pain is always aggravated by pressure.

Distension with spasm of the stomach may be distinguished from a similar condition of the colon, by the pain occupying a higher position in the abdomen (at or around the ensiform cartilage instead of—as in colic—the umbilical or hypochondriac regions), and by the percussion note elicited being deeper-toned and more prolonged than that which is produced by a distended colon. Besides, in colic the spasmodic contraction of the colon, producing borborygmi, may be traced by the

hand, or may be even seen, and there is tenesmus.

It should be borne in mind that enteritis or peritonitis may follow colic, when the pulse may become frequent, hard, and small, or frequent and soft, the temperature increased, and the seat of inflammation becomes tender.

**PROGNOSIS.**—Colic almost always ends in recovery, preceded by free evacuation of the bowels. Unfavourable signs are those arising from inflammation or intestinal obstruction.

**TREATMENT.**—In the first place the etiological indications should be met. The irritating contents of the bowels should be dislodged by purgatives combined with sedatives, such as calomel (five or eight grains) or rhubarb (twenty grains), with opium (one grain), followed by repeated doses of some saline aperient, such as sulphate of magnesium or potassium, with tincture of belladonna, henbane or opium, and spirit of chloroform, until free action of the bowels is obtained.

A suppository containing half a grain each of hydrochlorate of morphine and extract of belladonna, or a subcutaneous injection of morphine, may secure immediate relief from pain before aperients have time to act. Large warm enemata often relieve quickly. Other suitable measures are—the warm bath, friction with warm oil or stimulating liniments, hot-water fomentations, steamed flannels, mustard or turpentine stupes, flannel bags containing hot chamomile flowers or heated sand, the stomach-warmer filled with hot water, and large linseed and mustard poultices. The diet should be liquid.

In the prophylactic treatment the diet should be strictly regulated; lodgment of irritating solids and gases within the bowels should be prevented (*see* CONSTIPATION; FLATULENCE; and STOOLS); and the abdomen and feet should be kept warm by a flannel roller or belt and thick woollen stockings, or by a foot warmer. GEORGE OLIVER.

**COLLAPSE.**—**DEFINITION.**—Collapse is a condition of nervous prostration. When it is extreme, the vital nervous functions are in a state of partial, sometimes nearly complete, abeyance. It may terminate in death, or be followed by gradual reaction and complete recovery.

Collapse and shock have usually been classed together, but it is not accurate to do so. It is true that the ganglionic centres of the medulla oblongata are more or less profoundly involved in both, and that the two conditions possess many symptoms in common, dependent upon the derangement of function of one or more of these centres. Some confusion is attributable to the fact that shock is a term applied not only to a state or morbid condition, but to the cause which most frequently produces that condition—a violent impression or 'shock' to the nervous centres (*see* SHOCK). Collapse arises from many

different causes, shock being one, of which collapse may be regarded as a final and extreme degree, and into which it often imperceptibly passes. Collapse may occur under conditions where there has been no antecedent state of shock. Collapse presupposes previous nervous exhaustion, while shock may instantly appear in a healthy individual.

**ÆTIOLOGY.**—Any severe injury, especially if attended by profuse and sudden hæmorrhage, may terminate in collapse, such, for instance, as the rupture of one of the abdominal viscera, a penetrating wound of the chest or abdomen, or a wound of the heart or of a large artery. Extensive burns or scalds frequently give rise to typical collapse; and severe and prolonged pain is capable of causing it. Rupture of the heart or of an internal aneurysm, if the patient do not immediately die, causes extreme collapse. Certain poisons, as tobacco and arsenic, will also produce this condition. It is an advanced stage of some diseases, as, for instance, of Asiatic cholera; severe drastic purgation also, or prolonged vomiting, from whatever cause, may occasion it. The pernicious malarious fevers and yellow fever often end in collapse. In acute yellow atrophy of the liver symptoms of severe nervous disturbance, resulting in a species of collapse, sometimes suddenly supervene. Pyæmia, septicæmia, prolonged narcosis, frequently terminate in collapse.

**SYMPTOMS.**—The severity of collapse depends on the nature of the cause, and on the age and physical and mental vigour of the individual. It may vary from a moderate to an extreme degree. A moderate amount is seen in the course of fevers and some other diseases, but this neither modifies the progress of the malady nor attracts the notice of the patient, causing chiefly peripheral coldness. From this trifling amount collapse may pass to the most intense form, where the patient scarcely differs in outward semblance from a dead body. A superficial inspection will fail to detect the existence of the functions of respiration and circulation. Vitality may be said to have reached its minimum. In well-marked collapse from severe injury or loss of blood, the pulse at the wrist may be almost or wholly imperceptible; the heart's action scarcely audible, or very rapid, fluttering, and irregular; the surface of the body, the face especially, is deadly pale and cold, and the skin moist with clammy sweat; the respirations are very feeble, slow, and irregular, accompanied by sighing or gasping inspirations at intervals; the expression and character of the face are lost; the features are sunken and relaxed; the eyes are dull, glassy, staring, or languidly rolling about, and the conjunctivæ perhaps insensible to the touch; the nostrils are dilated; the sensibility of the whole body is diminished; and the muscular debility is

extreme. The patient lies on his back, without a trace of voluntary effort. If a limb is lifted it falls back again as if dead. Yet the consciousness and senses may in many cases be almost unimpaired; if roused by repeated questions, the sufferer will with visible effort make a coherent though, probably, inadequate reply.

If relief be not given, the respirations may become slower and slower till each one appears the last, when a sudden sigh shows that life is still present; finally the pulse and heart's action become more and more faint, and death results from pure asthenia. A condition closely resembling traumatic collapse is often witnessed in the last stage of cholera, when in an extreme degree the patient almost resembles a corpse save for the convulsive movements induced from time to time by the painful cramps. The surface is pale or bluish and covered with profuse sweat, but is at the same time cold to the touch. The hands and extremities are icy cold; the tongue is cold, and so also is the breath, which is gasping and paroxysmal; no pulse can be felt at the wrist; the eyes and features are sunken; the mind is apathetic, but nevertheless the consciousness may be perfect, and the patient able to respond to questions with a strong voice. Severe purging and tobacco-poisoning produce a condition very like that described as traumatic collapse.

Some cases of malignant fever terminate in collapse, which is characterised by extreme anxiety, by pallor or lividity of the face and surface, coldness of the skin, sweating, and a small, frequent, and irregular pulse.

A decrease of animal heat, especially in the external parts, is characteristic of collapse. The temperature of the internal organs varies; and there may be collapse with high internal temperature. This occurs in cholera, intense fevers, and some forms of septicæmia; or the converse may obtain, as is frequently witnessed in the collapse of dissolution. Collapse from loss of blood differs from syncope, although the latter may be described as an acute and transient form of collapse. In syncope the prominent symptom is loss of consciousness, which in collapse may be almost or quite perfect.

For the **PATHOLOGY** and **TREATMENT** of collapse, see **SHOCK**.

WILLIAM MAC CORMAC.

**COLLAPSE, Pulmonary.**—A condition in which the lung is simply more or less devoid of air. See **LUNG**, Collapse of.

**COLLIQUATIVE** (*colliqueo*, I melt). A term which originated in the belief that in certain conditions the solid parts of the body melted away, and were carried off as liquid discharges. The word is now generally applied to the copious sweats and diarrhœa which occur in certain wasting diseases, such as phthisis.

**COLLOID** (κόλλα, glue; and εἶδος, like). A peculiar morbid product resembling in its characters glue or jelly, and found associated with cancer and other forms of new-growth. See CANCER; and DEGENERATION.

**COLON, Diseases of.**—**SYNON.**: Fr. *Maladies du Colon*; Ger. *Dickdarmkrankheiten*.—The colon participates to a varying extent in the lesions and derangements of dysentery, typhoid fever, enteritis, peritonitis, and other affections. The special disorders to which it is most liable are intimately connected with its anatomical and physiological peculiarities. The colon is a distensible membranous tube, of large capacity, with chiefly solid contents, which are propelled slowly onwards by the muscular contractions of the walls. The moving force and the resistance offered to it are often too finely balanced, so that whenever the energy of the former is somewhat reduced, an accumulation of excretory products is apt to be determined. Hence arise retention of feces and gases, constipation, and consecutive evils, such as colic, colo-enteritis, or ulceration of the colon.

**I. Atony and Dilatation.**—**DEFINITION.** Loss of contractility of the walls of the colon, leading to accumulations, dilatation, and other sequelæ.

**ÆTIOLOGY.**—The causes of torpor or atony of the colon are mainly those of constipation—sedentary, indolent, and luxurious habits, over-stimulation of the bowels by coarse foods, purgatives, and enemata, a sluggish and lymphatic temperament, old age, and general debility or exhaustion, as after a long and tedious illness (see CONSTIPATION). Whenever the walls of the colon are distended by solid or gaseous accumulations, the contractile power is apt to be enfeebled, leading to further retention, loss of tone, and dilatation.

Atony of the colon is an important element in the pathology of constipation. The colon is apt to become greatly dilated throughout, or mainly so in certain portions, such as the cæcum and sigmoid flexure, behind some cause of obstruction—stricture, misplacement, elongated meso-colon, lodgment of feces, &c.; but instances of even excessive dilatation are recorded without the *post-mortem* discovery of a mechanical cause. When, however, dilatation results from obstruction, there will be found hypertrophy of the muscular coat of the bowel. Tympanitic distension of the colon from paralysis of the sympathetic occurs in peritonitis and in certain fevers, such as typhoid.

**SYMPTOMS.**—Torpor of the colon may be indicated only by constipation. There are usually the ordinary signs of retention of flatus or feces. In hysteria, and in inflammation of the bowels or peritoneum, flatus is apt to accumulate rapidly, and to produce great distension of the colon. Fæces

may collect and form large tumours in any part of the large intestines, but especially in the cæcum and sigmoid flexure. See STROOLS.

Fæcal and gaseous accumulations in the colon resulting from atony may produce the following effects, directly or remotely connected with them:—

(a) *Local.*—1. Colic. 2. Inflammation of the walls of the colon, or of the mucous and submucous coats, and ulceration. 3. Disturbances from pressure. Thus flatulent distension and fæcal accumulation encroaching on the cavity of the thorax, and impeding the descent of the diaphragm, may cause feeble respiration, dyspnoea or short and rapid respiration, palpitation and irregular action of the heart or upward displacement of this organ, with remote effects arising from a disturbed circulation in the brain, such as giddiness and headache. On the other hand, a distended cæcum or sigmoid flexure, pressing on veins and nerves, may induce œdema, numbness, and cramps of the right or left lower extremity. 4. Retarded digestion, derangement of the stomach and liver, and intestinal obstruction.

(b) *General.*—The absorption of excrementitious matters may lead to widespread general effects, indicated by a sallow, earthy, or dirty complexion, lassitude, debility, offensive breath, loaded urine, and other symptoms. Chlorosis has been attributed to this cause.

**TREATMENT.**—Atony of the colon is usually a chronic disorder demanding prolonged treatment. The hygienic and dietetic rules laid down in the article CONSTIPATION require in most cases to be supplemented by medicines. The most satisfactory results follow a course of tonics combined with aperients, such as iron, quinine, strychnine, and belladonna, with aloes, colocynth, or rhubarb. The purgative should be adjusted to each case, so as to secure no more and no less than a regular and efficient evacuation; and while the loaded colon continues to be thus relieved, the dose should be very gradually reduced. This tonic-aperient course may be greatly aided by local stimulation of the colon, as by massage, electricity, and cold-water compresses or abdominal douches (see CONSTIPATION). The abdomen should be supported by a belt or roller. Bretonneau and Trousseau strongly advised a course of belladonna, giving gr.  $\frac{1}{7}$  of the extract, or of the powdered leaf, as a pill in the early morning—the stomach being empty; then two such pills, if in four or five days the bowels do not respond; and increasing the dose, but not beyond that contained in four or five pills in twenty-four hours. A teaspoonful of castor oil may be given twice a week to aid this course of treatment. Flatulent distension of the colon in the elderly, and in females at the climacteric period, is often greatly relieved by the prolonged use of a pill containing the compound asafetida pill and extract of nuxvomica, after meals.

In excessive gaseous dilatation of the colon (as in volvulus of the sigmoid flexure), producing much distress from dyspnœa, pain, and vomiting, puncture by a fine trochar or aspirator-needle has been successfully resorted to as a palliative measure.

II. **Stricture.**—Stricture of the colon may occur in any part, but is most common in the sigmoid flexure and descending colon. It is limited to adults. It more commonly arises from cancer than from the cicatrising of an ulcer (simple stenosis). In non-cancerous stricture a history of dysentery is important—though a long interval (even years) may have elapsed since the attack. The stricture declares itself by setting up symptoms of intestinal obstruction—there being at varying intervals attacks of paroxysmal, shifting, colicky pain across the navel, with constipation (or constipation alternating with diarrhœa) aggravated by purgatives, becoming more and more frequent and associated with vomiting—when, as a rule, the difficulty ceases to be intermittent. Large fecal masses may often be felt above the site of obstruction. In stenosis of the sigmoid flexure there is sometimes tenesmus, and the motions are flattened; the stricture can be reached when the whole hand is introduced into the rectum. The motions are not, as a rule, altered in shape when the stricture is situate in the higher part of the colon. The site of obstruction may sometimes be determined by auscultating the abdomen while water is being gently and intermittently injected into the rectum—the observer failing to hear the stream above the stricture. The duration of the cancerous as well as of the simple forms averages from five to six months.

**TREATMENT.**—The treatment of stricture of the colon is further referred to in the article on **INTESTINAL OBSTRUCTION.**

III. **Inflammation.**—**SYNON.:** Colitis; Colonitis; Colo-enteritis; Fr. *Colite*; Ger. *Entzündung der Schleimhaut des Kolons.*

An inflammation, leading to ulceration of the mucous membrane and submucous connective tissue of the colon, producing lesions indistinguishable from those of dysentery, has been pointed out by Copland and Parkes. Colitis is said to be a non-specific local affection, commencing in the submucous tissue, and subsequently attacking the mucous membrane with its glandular structures—the primary seat of dysenteric inflammation. As in dysentery, the inflammation induces gangrenous destruction and ulceration of the mucous membrane and underlying cellular tissue.

A *catarrhal* form of colitis is apt to occur in measles. It often happens that the morbillous catarrh of the intestines exhausts itself by attacking the large intestine, producing that special form of colitis characterized by tenesmus and glairy bloody stools.<sup>1</sup>

<sup>1</sup> Trousseau, *Clinique Médicale.*

Inflammatory diarrhœa, particularly in children, often terminates similarly.

Colitis arising from *retained excreta* may involve the entire wall of a circumscribed portion of the colon, commonly the ascending colon and sigmoid flexure, or may be confined to the mucous and submucous tissues. In fecal retention the mucous follicles of the colon may become obstructed, and the distension resulting therefrom may lead to inflammation and ulceration. Irritation of the mucous lining of the colon from the lodgment of feces may extend to the lymphatic vessels and glands. The glandular enlargement cannot, however, as a rule, be recognised during life. In colitis there are usually colicky pains, intestinal distension, and diarrhœa alternating with constipation; and the stools are often coated with masses of mucus.

**TREATMENT.**—The treatment of colitis consists in the local application of fomentations, poultices, opium enemata, or morphine suppositories; and in the use of gentle laxatives, such as castor oil, combined with sedatives, such as opium, belladonna, or henbane. The catarrhal form generally terminates in spontaneous recovery. Trousseau advised the use of albuminous injections, or of injections containing about half an ounce of water and nitrate of silver—from  $\frac{3}{4}$  to  $1\frac{1}{2}$  grains; or sulphate of copper or sulphate of zinc—from  $3\frac{1}{2}$  to  $4\frac{1}{2}$  grains. The diet must be very carefully ordered.

IV. **Displacements.**—The parts of the colon most liable to displacement are the transverse colon and sigmoid flexure. The former may descend as low as the pubes; the latter may occupy any position between the left iliac region and the right side of the abdomen. Usually the mesocolon is elongated; there is adhesion between the displaced part and the new site; and, the longitudinal bands being elongated, the loculi are obliterated. Displacements are most apt to occur in those who have long suffered from constipation, retention of feces, chronic dysentery, hernia, or from encysted or other tumours. They may lead to complete obstruction, and cannot usually be recognised with certainty during life.

V. **Diverticula.**—A *loculus* of the colon from repeated accumulation may become so distended as to form a lateral appendix. Such a diverticulum when loaded with feces may be felt through the abdominal wall as a distinct tumour, which may collapse when pressed between the fingers.

GEORGE OLIVER.

**COLORADO SPRINGS, in Colorado, U.S.A.**—A clear, cold, and very bracing climate, with great dryness and diathermancy of the atmosphere; 6,028 feet above the sea. No snow in any quantity, and consequently no snow-melting season. Dry

and dusty winds in spring. Camping out at nearly all seasons tolerably safe. A high-altitude station, useful in asthenia and in chronic phthisis, especially with limited lesions and no pyrexia. The name of 'springs' is added from the proximity of Colorado City to Manitou Springs, six miles distant. See CLIMATE, 'Treatment of Disease by.

**COLOUR-BLINDNESS.**—A defect of vision, the subject of which is unable to distinguish certain colours. See VISION, Disorders of.

**COMA** (κῶμα, deep sleep).—A condition of profound insensibility. See CONSCIOUSNESS, Disorders of.

**COMA-VIGIL** (κῶμα, deep sleep; and *vigil*, wakeful).

**DEFINITION.**—A symptom, or set of symptoms, where continuous sleeplessness is associated with partial unconsciousness.

Coma-vigil occurs towards the end of diseases in which the nervous system is involved either directly or indirectly, especially where sleeplessness has been a symptom in the earlier part of the disease. Thus it frequently appears towards the end of an attack of typhus or of delirium tremens, when these are about to terminate fatally.

**SYMPTOMS.**—The patient lies quiet with his eyes half-closed, inattentive to everything around, but not absolutely unconscious. If the eyelids are touched, they are closed, and perhaps the head is slowly turned away. The eyes have a dull, half-glazed look, and slowly follow any moving object near them. The pupils are neither much dilated nor contracted, and they move under the influence of light, but very sluggishly. The mouth is generally somewhat open and dry, as are also the lips. The power of swallowing is much impaired: if a small quantity of fluid be put into the mouth, an effort is made after a short time to swallow it, and this effort is for a time successful; but after the symptoms have been present for some time, the effort is so feeble that no result follows. The patient lies mostly on the back; if turned on the side, he either remains as placed, or often slowly turns to the former position. The limbs are occasionally moved a little; and if the hand or arm be raised, a slight resistance is offered. If the bladder or the rectum be emptied, there is slight consciousness of the act, as if a feeling of discomfort preceded it. The pulse is quick and weak. The respirations are weak, but otherwise normal. The symptoms continue unbroken throughout, nothing like natural sleep occurring.

**PATHOLOGY.**—As being little more than a symptom, coma-vigil has strictly speaking no pathology. It seems to coincide with the gradual suspension through exhaustion of the functions of the nervous centres; the cerebral hemispheres being nearly if not quite inactive, while the action of the rest of the centres

is kept up weakly but continuously, till the little remaining nervous power is exhausted, when death ensues. It differs from coma inasmuch as in the latter the medulla oblongata is the only centre left active, the functions of the rest being entirely suspended. It differs from concussion, inasmuch as the symptoms of the latter attending the temporary unconsciousness are more those of irritation than of pure suspension of function.

**DIAGNOSIS.**—Coma-vigil is distinguished from coma by the presence of a certain amount of consciousness, by the quick pulse, and by the absence of stertorous breathing. It is distinguished from concussion of the brain by the pupil not being contracted, by the history of the case, and by the absence of coldness of the skin, and of any sign of shock.

**PROGNOSIS.**—The prognosis is unfavourable: coma-vigil is almost invariably a fatal symptom. It may last from a few hours to three or four days; from twenty-four to forty-eight hours being the most common duration. It may deepen into actual coma; but more usually the symptoms change but little, save that the pulse becomes quicker and weaker, and the respiration more feeble, and death by asthenia then results.

**TREATMENT.**—Coma-vigil does not call for treatment directly itself, but is an urgent indication for nutritive and stimulant measures calculated to relieve the primary disease.

R. BEVERIDGE. JOHN BANKS.

**COMEDONES** (*comedo*, a glutton).—**SYNON.**: Grubs.—This is the name applied to the little cylinders of sebaceous and epithelial substance which are apt to accumulate in the follicles of the skin, and to appear on the surface as small round black spots. When squeezed out they have the appearance of minute maggots or grubs with black heads, and thence have derived their name. They may occur in all parts of the body where sebaceous follicles exist, but are most common on the face, the nose, the neck and shoulders, the breast, and within the concha of the ears, in the latter situation often attaining a considerable size. The accumulation of this substance is due to want of expulsive power of the skin, and to the slight impediment which is afforded by the aperture of the follicle to its exit. When squeezed out, a comedo is found to vary in colour, in figure, and in density, according to the period of its detention. When recent, the comedones are soft and white, and modelled into an exact cylinder by compression through the mouth of the follicle. If impacted for a considerable time, they acquire the yellow tint, the transparency and hardness of horn; they assume a bulbous figure from the dilatation of the follicle below the constricted orifice of the epidermis; and by their bulk they sometimes stretch the hair-follicle so far as to obliterate it completely. Besides

their usual composition of sebaceous substance and epithelial cells, they frequently contain lanuginous hairs, and not rarely the entozoon folliculorum in its different phases of development (*see* ACARUS). When they raise the pore into a minute pimple they have a similitude to acne punctata, and might be mistaken for that affection; whilst the black spot on the summit of conical aene is due to a comedo.

**TREATMENT.**—Comedones are most frequently met with in young persons in whom the powers of the constitution are not yet established, and who are benefited by generous diet and tonic treatment. Locally, soap and water with plentiful friction and abluion will be found of great service; and, as an astringent, a lotion of perchloride of mercury in emulsion of bitter almonds (two grains to an ounce) and spirits of wine; or a lotion of carbolic acid.

ERASMUS WILSON.

**COMPLICATION** (*con*, with; and *plico*, I fold).—It is difficult to give a strict definition of what ought to be included under the term *complication*; but the word signifies the occurrence during the course of a disease of some other affection, or of some symptom or group of symptoms not usually observed, by which its progress is therefore 'complicated,' and not uncommonly more or less seriously modified. The difficulty lies in determining what should be looked upon as essentially part of the original disease, and what as a mere accidental occurrence. For instance, many regard the cardiac affections which so often arise during the progress of acute rheumatism as a part of the complaint, others as complications. The same remark applies to the relationship of renal disease to scarlatina, as well as to numerous other cases.

Complications arise in different ways. They may, as just indicated, be considered as developments of the original morbid condition, resulting from the same cause and being more or less allied; or they are independent and accidental, of which an illustration is to be found in the association of ague with scurvy or dysentery, or in the co-existence of two or more of the exanthemata. The most important class of complications, however, are those which follow the primary disease as more or less direct consequences. These may further be induced in various ways. Thus, for example, in febrile diseases secondary lesions are liable to arise as a result of changes in the blood; a mechanical act, such as cough, may lead to complications in the course of phthisis and other pulmonary affections; cardiac diseases frequently bring about consecutive changes in other organs, by inducing obstruction of the venous circulation; or emboli may originate under certain conditions and produce their usual consequences. It is of great practical importance to be acquainted with the complications which are

liable to be met with in various diseases, and especially in those which are of an acute nature, in order that measures may be taken for their prevention, and that they may be recognised and treated at the earliest possible period, if they should occur.

FREDERICK T. ROBERTS.

**COMPOUND GRANULAR CORPUSCLES.**—Formerly these microscopic objects were regarded as of inflammatory origin, and as affording positive evidence of the occurrence of inflammation. Hence they were termed 'compound inflammation globules' (Gluge). Almost all pathologists now, however, recognise the fact that they are not products of an inflammatory process, but result either from the degeneration of pre-existing cells, in which protein and fatty granules accumulate, or, perhaps, from the aggregation of granules originally distinct, which are present in abundance in degenerating tissues. They may even be formed out of the cells of morbid products, such as cancer. These compound granular corpuscles derive their name from the fact that they consist of a large number of minute granules aggregated together, and they either present a delicate cell-wall, or this cannot be detected. Occasionally there is an appearance of a nucleus in the centre. *See* CELL.

FREDERICK T. ROBERTS.

**COMPRESS.**—A compress is made of folds of lint or other material, and is used for the purpose of producing pressure, or as a pad by which hot or cold water or medicinal agents may be applied to the surface. In the latter case the compress may be rendered waterproof by being covered with a piece of gutta-percha tissue or mackintosh-cloth. *See* HYDROPATHY.

**COMPRESSIBLE.**—A term implying comparatively slight resistance, and applied specially to the pulse when it yields readily under the finger. *See* PULSE, The.

**COMPRESSION of the Brain.**—*See* BRAIN, Compression of.

**COMPRESSION of the Lung.**—*See* LUNGS, Compression of.

**CONCRETION** (*con*, together; and *cresco*, I grow).—**SYNON.**: Calculus; **Fr.** *Concrétion*; **Calcul**; **Ger.** *Concrement*.

**DEFINITION.**—An unorganised body, formed either in one of the natural cavities or canals, or in the substance of an organ, by the deposit of certain solid constituents of the fluids of the part. In the widest sense of the term, concretions comprehend calculi.

**ENUMERATION AND CLASSIFICATION.**—The following classified list includes the principal varieties of concretions:—

1. In *glandular structures*: lacrymal, salivary, pancreatic, prostatic, seminal, urinary, hepatic, sebaceous, and mammary.

2. In the *circulatory system*: cardiac, and venous (phleboliths).

3. In *closed sacs*: peritoneal, and articular.

4. In *culs-de-sac*: bronchial, pulmonary, nasal, tonsillar, laryngeal, gastric, intestinal, præputial, uterine, and vaginal.

5. In the *substance of tissues* and new formations, especially in the nervous system: corpora amylacea.

6. *Various*: such as the concretions on the teeth known as 'tartar.'

**GENERAL CHARACTERS AND NUMBER.**—Concretions are generally firm or even of stony hardness; but they may be soft and friable. Their colour varies from white to black through shades of yellow and red. Concretions occur either singly or in groups; and their shape and size, as well as the characters of their surface, vary considerably with their number: single concretions are more frequently larger, rounded, and less smooth than multiple specimens, which often present facets and polished surfaces. Many concretions are composed of concentric laminae.

**COMPOSITION.**—The chief constituents of concretions are inorganic, that is, mineral salts, in a basis of organic matter. The bulk of the salts are carbonate and phosphate of calcium and magnesium, with smaller quantities of alkaline compounds. The organic basis is composed of albuminous substances, mucus, cholesterin, and colouring matters.

**MODE OF FORMATION.**—Concretions are generally derived from the solid constituents of vital fluids, whether physiological or pathological. In most instances the fluids are delayed in the natural passages by some abnormal obstruction or dilatation; and under such circumstances a chronic inflammatory condition of the walls contributes greatly to the probability of mineral deposit. Most frequently—as in the formation of the salivary and biliary concretions—the fluid portions of the secretion escape by the natural outlet or are absorbed, while the solid constituents are deposited; the particles being either agglomerated around a nucleus, or deposited in centripetal layers upon the surface of the cavity. In other instances—intracardiac, peritoneal, and articular—a nucleus is furnished by a particle of fibrin, blood-clot, or growth, on which fresh deposits take place, while calcification proceeds in the interior. In a third series, examples of which are found in the alimentary canal, the basis of the concretion consists of foreign or indigestible matter, such as hair, a gall-stone, inspissated fæces, and masses of magnesium or iron salts. See CALCULI.

**EFFECTS AND SYMPTOMS.**—The functions of a part occupied by a concretion are generally more or less impaired; the neighbouring tissues frequently atrophy; and inflammation and ulceration are common results, ending probably in the escape of the body. The

concretion may be passed along a duct, and this process is generally attended with great pain; but concretions may remain where formed without causing symptoms. Occasionally they are spontaneously disintegrated or dissolved.

**TREATMENT.**—The treatment of concretions will be found discussed under the heads of the diseases of the organs where they respectively occur.

J. MITCHELL BRUCE.

**CONCUSSION** (*concutio*, I shake together).—This term is used to indicate a condition induced by a more or less violent shaking or physical commotion of the general system, or of some particular organ, whereby serious symptoms may be induced, but no definite lesion can be detected to account for them. The nerve-centres are the parts most liable to be thus affected, concussion of the brain or spinal cord being of considerable moment, giving rise to more or less complete abolition of their functions, though this effect is usually only temporary (see BRAIN, Concussion of; and SPINAL CORD, Diseases of). General concussion of the body is highly important at the present day, in connexion with railway accidents, after which persons seem to be uninjured, or only to be slightly shaken, but subsequently more or less grave symptoms, associated with the nervous system, set in. See RAILWAY ACCIDENTS, Results of.

FREDERICK T. ROBERTS.

**CONCUSSION OF BRAIN, SPINE, &c.**—See BRAIN, Concussion of; and SPINAL CORD, Diseases of.

**CONDYLOMA** (*κονδύλωμα*, a knob).—**SYNON.**: Fr. *Condylome*; Ger. *Feigwarze*.

This vague term has been used to describe at least two different things—namely, (a) papillomata, or warty growths in the neighbourhood of the anus and genital organs; and (b) the syphilitic lesions called mucous patches or mucous tubercles. Of these the former only will be dealt with here. The latter are described under MUCOUS PATCH.

**DESCRIPTION.**—Condyломата are commonly found in connexion with the constant moisture and irritation due to acrid secretions, whether natural or morbid, especially the discharges of venereal affections. The growths occur most frequently and attain the greatest size in dirty persons, in whom also they are most liable to become inflamed, ulcerated, and fissured. The enormous masses sometimes seen in pregnant women are often called 'cauliflower' growths.

**TREATMENT.**—Frequent washing, followed by the free application of some absorbent powder, such as oxide of zinc, is essential. When the growths are very large, or fail to disappear under caustics, removal by scissors, knife, or cautery will be necessary.

ARTHUR COOPER.

**CONFLUENT** (*confluo*, I run together). Applied chiefly to a variety of small-pox and other exanthemata, in which the eruption runs together or coalesces.

**CONGENITAL** (*con*, together; and *genitus*, begotten).—Existing at birth: a term generally applied to diseases such as *congenital syphilis*, or malformations such as of the heart, and *congenital clubfoot*.

**CONGESTION** (*congero*, I accumulate). Overfulness of vessels, caused by accumulation of their contents: generally applied to blood-vessels. See CIRCULATION, Disorders of.

**CONIUM, Poisoning by.**—SYNON.: Fr. *Empoisonnement par la Ciguë*; Ger. *Schierlingsvergiftung*.—All parts of the hemlock plant (*Conium maculatum*; Greek, *κόνειον*) are poisonous. Both the leaves and fruit are used in medicine. Its toxic properties were known in ancient times; the plant was used for the destruction of criminals by the ancient Greeks, and there is no doubt that Socrates was poisoned by it. Death from conium in this country has perhaps always been the result of misadventure or suicide; but on the Continent the active principle of the plant, *conine*, an alkaloid, has been administered for the purpose of wilful homicide, death resulting from a dose of 10 to 15 drops.

**ANATOMICAL CHARACTERS.**—The signs of asphyxia, engorgement of lungs and of the right heart, and a general venous condition of the blood, appear to be constant after death from conium. There is nothing else specially noticeable.

**SYMPTOMS.**—Preparations of conium, as well as the alkaloid, or mixture of alkaloids, known as *conine*, when taken in toxic doses, produce excessive muscular weakness, beginning in the lower limbs, and extending gradually upwards, with giddiness and disordered vision. These symptoms are in some cases preceded by nausea and vomiting, with dryness or burning pain in the mouth and fauces. There is a desire to remain quiet, and a peculiar heaviness or drooping of the eyelids, the patient lying with his eyes shut. This, and the impairment of vision, appear to be due to paralysis of the ocular muscles. The pupils may be natural, but later they become dilated. The pulse is slow till death is actually impending. The paralysis progresses gradually upwards, till eventually heart and respiration are affected, more especially the former. Convulsions and impairment of the mental faculties—hitherto intact—now set in; finally sensation is impaired, and death ensues from asphyxia.

**DIAGNOSIS.**—The paralysis of motion, progressing gradually upwards, with sensation long unimpaired, and the peculiar drooping of the eyelids, are perhaps diagnostic of the nature of the poison.

**PROGNOSIS.**—As no antidote is known

which counteracts the effects of conine, the prognosis must always be a guarded one, and will depend entirely upon the general condition of the patient.

**TREATMENT.**—The stomach must be emptied by the stomach-pump or syphon-tube, and well washed out. Emetics may also be used to evacuate the stomach. Tannin and other astringents must be freely administered, to precipitate the active alkaloid, and prevent its absorption. Castor oil, administered by the mouth or rectum, may aid the removal of the alkaloid when it has been rendered insoluble by tannin. Strong coffee, brandy, ammonia, and stimulants generally are serviceable, as may also be the hypodermic injection of ether. Hypodermic injections of 1-40th grain of sulphate of atropine are very promising, especially in the later stages; atropine acting as a respiratory and cardiac stimulant. Artificial respiration, and stimulation of the respiratory and cardiac functions by the use of electricity, ought not to be neglected when these are affected.

THOMAS STEVENSON.

**CONJUNCTIVITIS.**—Inflammation of the conjunctiva. See EYE AND ITS APPENDAGES, Diseases of.

### CONSCIOUSNESS, Disorders of.—

The disorders of consciousness are so numerous as to make it desirable briefly to consider them in one article, with a view to their classification and the better comprehension of their mutual relations. We shall, therefore, here group and arrange the varied morbid conscious states, not aiming to produce a strictly scientific classification so much as one which will be practically useful.

1. **Exaltation.**—Under this head may be ranged certain states of consciousness more or less distinctly bordering upon the unnatural, to be met with in persons under the influence of 'mental excitement' from various causes, as from sudden good news, or generally pleasant surroundings; also from a slight degree of poisoning by alcohol, opium, hashisch, or other drugs; or from an early stage of some forms of insanity, or of delirium. In this state of mental exaltation the individual's powers of perception, apprehension, recollection, thought, emotion, and volition, would seem to be all more or less intensified, just as in that of hebetude or dementia they are diminished, and consciousness is proportionately dwarfed.

2. **Perversions.**—Many of the various defects here to be referred to are very partial in the extent to which they implicate consciousness, though others are general. In what is known as an *illusion* some object of sense is not correctly perceived; or, in other words, some sensorial impression is quite wrongly interpreted—as when a feverish or a maniacal patient, looking at some inanimate object, declares that it is a cat or a dog.

about to fly at him, or, hearing even the slightest noise in any part of his room, interprets it to be the voice of some friend or imagined enemy. In the case of an *hallucination*, however, forms are declared to be seen, or voices heard (by a patient suffering from delirium tremens, for instance), where no appreciable external realities could have started the notion. And in these cases, it is not that the patient sees or hears without believing; he implicitly believes that the visions or voices, which have been conjured up subjectively by the mere disordered working of his own brain, have a real existence in the outside world. It is necessary to make this distinction, because it is by no means uncommon, in regard to the olfactory sense (especially in some epileptics), for odours or smells to be perceived which the patient soon comes to know are purely subjective or devoid of any external correlative.

Hallucinations and illusions, moreover, though occasionally existing alone, are quite commonly associated with a very important and more general derangement of consciousness, namely, *delirium*. This is a symptom very common in many fevers, in certain low states of the system, after severe frights, in inflammatory or other lesions of the brain and its membranes, as a result of some narcotico-irritant poison, or occasionally in a person who is recovering from an epileptic attack, or from the stupor sequential to a series of convulsive attacks. The state itself varies much in intensity. Three fairly distinct types exist. In (*a*) *low or muttering delirium* the patient lies still and more or, less heedless of what is occurring around; or, if heeding at all, the impressions which he receives give rise to erroneous perceptions (illusions), which are woven into the incoherent fabric of his rambling thought. In (*b*) *delirium tremens* the patient is more restless; tremors of the limbs and of the muscles of the face are often easily induced; hallucinations of sight and hearing are common; and the character of the delirium reveals that the patient is, to an unusual extent, possessed by fears, terrors, and other emotions of a depressing type. In (*c*) *wild or raving delirium* we have to do with a much more active state. The patient raves loudly and incoherently, more in regard to his fleeting dream-like thoughts than in connexion with external impressions, of which he is more or less heedless. He is often violent in demeanour, and difficult to be restrained, persons in this state being capable of great and prolonged muscular exertion. The bodily activity accompanying this form of delirium is, in fact, just as characteristic as the great intensity of the mental processes. It is met with occasionally in some fevers, but more commonly in meningitis and in acute mania.

In its early stages delirium is principally

noticed during the transition-period between waking and sleeping—at times, that is, when the nervous system most needs the re-invigorating influence of sleep. It is in these cases, too, that beef-tea or stimulants may for a time dispel all traces of the wandering thought. Whilst illusions and hallucinations enter largely into the mental activity of a delirious patient, *delusions* also are generally well-marked components. That is to say, the person becomes for a time possessed by an idea, notion, or fancy, for which there is no real warranty, though he believes and wishes to act as though it were true.

Somewhat allied to delirium in nature, though much lower in intensity as a mental process, is that *incoherence* of thought which is met with in many chronic maniacs, or in non-febrile patients suffering from various organic brain-diseases. In its slighter degrees this incoherence displays itself as mere 'rambling' talk; the patient has not sufficient brain-power to follow up the main subject of thought, and is frequently diverted into collateral channels. This, which is a natural state with some persons, may be distinctly indicative of disease in others whose mental power has previously been of a more vigorous type. At times the incoherence is seen to be governed principally by mere verbal suggestion, the patient being led away from point to point in new directions, owing to the associations of some word which has been used becoming for the time dominant. This state is often well seen in the sub-acute exacerbations of chronic mania, though it may occur also where multiple softenings or indurations of the brain exist. At other times the incoherence is more absolute—wayward transitions from subject to subject, connected by no discoverable bond, rapidly following one another. The result in such a case is a mere unmeaning jumble of words, interspersed here and there with brief propositions having a limited significance of their own, though often wholly unrelated to that which precedes or follows.

*Hypochondriasis* is a perverted state of consciousness, having some resemblance to that of illusion, but in which some internal or visceral state becomes the starting-point of impressions (possibly not actually painful) which, when magnified and perverted as they are in the mind of the patient, fill him with false and gloomy apprehensions of various kinds. This perversion of consciousness is more generalised than that which exists in the case of illusion; and also, instead of being a more or less temporary defect, it is one that may last for weeks, months, or even years. The state of mind of an hysterical patient is often not altogether different from that of the hypochondriac.

3. **Partial Loss.**—Defects of this order are numerous and may exist in great variety. They may implicate almost equally nearly all

the varieties of conscious mental activity, or some more than others. They may be either congenital, or acquired during the life of the individual.

In *idiocy* we may have from birth defect in the power of concentrating the attention, a defective power of apprehension and of thinking, and a defective volition, shown alike by an inability to guide or control thought, and by a deficient vigour of bodily movement. Again, as a result of epilepsy, of organic brain-disease, or of injuries to the head, the patient may gradually lapse into such a condition from one of health, so as to become, as it is termed, 'demented.' Whilst this state of *dementia* may supervene at any age, it is much more common as a consequence of the brain-diseases frequent in advanced life. There is, moreover, a form known as *senile dementia*, in which without any typical disease, but as a consequence of impaired tissue-vitality and diffused degenerative changes throughout the nervous system, the mental faculties undergo a more marked degradation than is usually met with in old age. This condition in its minor degrees goes by the name of *hebetude*. In all such states or grades of idiocy and dementia, we meet with an undue tendency to sleep in the daytime as a result of the listless and languid mental condition. This is but another sign of the general lowering of conscious vigour.

Here we must include, also, a peculiar group of conditions, having some alliance with one another, and which are all characterised by loss of consciousness to some extent, either partial in range or general. They are—*reverie*, *somnambulism*, *ecstasy*, *coma-vigil*, *catalepsy*, *hypnotism*, and *trance*. They are merely enumerated here, but are defined or described in their several places. In the last of these conditions the loss of consciousness, in the ordinary acceptation of the term (namely, loss of perceptive power), is so absolute, that some may think it ought rather to be included in the next section. Loss of perceptive power, however, would not seem to be absolutely synonymous with loss of consciousness. There is good reason to believe, for instance, that where the influence of chloroform and other anæsthetics is not pushed to the fullest extent, a condition of *anæsthesia* intermediate between slight and profound is produced, in which, whilst there is absolutely no consciousness for external impressions, so that pain is altogether unfelt, there is still a certain amount of cerebral activity—as evidenced by rambling and indistinct speech on subjects altogether apart from what the surgeon may be doing. There is mental activity clearly, though the nature of this, as revealed by the patient's speech, may preclude the notion that pain is at the time being felt. Sensorial consciousness is blotted out, whilst a kind of ideational con-

sciousness remains. We have an approximation to such a condition, also, in the case of *sleep* when dreams are rife. But here sensorial consciousness is not completely in abeyance. Again, in certain rare and anomalous epileptiform attacks we may find the patients, after the first paroxysms, bereft of some senses, though not of others. They may hear what is said by those around them, though they continue for a time quite unable to see or speak.

**4. Complete Loss.**—In very profound sleep (*sopor*), in that prolonged form of it in which the person, if he can be momentarily roused, drops off again immediately (*lethargy*), and also in profound *anæsthesia*, there is complete loss of consciousness. The terms *sopor* and *lethargy* are now rarely used, and authors are not even agreed as to the precise state which would be designated by the latter word. It is sometimes regarded as a synonym for 'trance.'

In *syncope* we have insensibility resulting from a cutting off of the proper supply of blood to the brain; whilst in *asphyxia* we have a like result following upon an interference with respiration, and a consequent engorgement with impure blood.

A condition of *narcosis* or profound insensibility may result from opium or other drugs and poisons, amongst which alcohol is to be included as one of the most common producers of such a state. It may also be due to the deficient elimination of waste products by the kidneys, when 'uramic coma' is produced; or to the abnormal production of chemical compounds in the system, which lead on to blood-poisoning, as in 'diabetic coma,' and in the final stages of septic poisoning.

Complete loss of consciousness exists for some time during the ordinary form of *epileptic fit*, or during an attack of convulsions; though in other epileptiform fits, not infrequently met with—having some of the characters of hysterical convulsions—there seems to be a loss of sensorial consciousness only (loss of perception), whilst a certain amount of ideational consciousness remains. In *apoplexy* also there may be for hours or days a more or less profound loss of consciousness. In the less profound attacks, as well as after an epileptic fit or an attack of convulsions, the loss of consciousness is not complete, and we have a condition now commonly known as *stupor*. This state is also frequent as a result of concussion or other injuries of the brain, and it occasionally follows a severe fit of hysterical convulsions. It may last for hours, days, or even weeks in some cases. In it the patient lies with his eyes closed, taking no heed of what is passing around, though he may show obvious signs of feeling when touched or pinched, and may be capable of being momentarily roused, so as to give a short monosyllabic answer if slightly shaken or spoken to in a loud voice.

On these occasions, signs of impatience are often shown. Though such a patient will not ask for food, he will often drink freely when it is offered. He will of his own accord, when his bladder is full, sometimes get out of bed, find the chamber-pot, use it, and return to bed without saying a word—and then speedily relapse into his previous state of stupor. When the insensibility is more profound, both urine and fæces are passed incontinently.

The state just spoken of is referred to in this section because it is so intimately allied to and connected by all sorts of transition conditions with another, known as *coma*, in which the loss of consciousness is more complete and absolute. There are different degrees of stupor and there are different degrees of coma; the former is commonly spoken of as slight or deep, whilst a comatose condition, coma, and profound coma (the latter being what the older writers termed *carus*) are the phrases ordinarily used to denote the increasing insensibility of the graver state, which is more especially characteristic of the apoplectic condition. Coma may result from long-continued exposure to cold, from sunstroke, from poisons of various kinds, from erysipelas of the head and face, from inflammations of the meninges, multiple embolisms, the effects of hyperpyrexia, or from cerebral hæmorrhage. The most common cause of very profound coma is cerebral hæmorrhage (apoplexy). In this condition the breathing is often loud and stertorous, and consciousness is entirely obliterated, so that there is an utter absence of reflex movements when a limb is pinched or when the conjunctiva is touched. The patient in the deeper forms of coma often cannot be roused at all, even for a moment; and if this state does not terminate in one way or another before the expiration of twenty-four hours, or if it does not gradually pass into one of mere stupor, a fatal result may be considered imminent.

H. CHARLTON BASTIAN.

**CONSTIPATION** (*con*, together; and *stipo*, I cram).—**DEFINITION.**—Slow passage of the fæces from the cæcum to the anus, leading to infrequent or incomplete alvine evacuation, and to retention of fæces.

**ÆTIOLGY.**—The causes of constipation may be *local*—an impediment to the onward movement of the fæces in the large intestine or from the rectum; or *general*—pertaining to habits, diet, and other conditions.

**Local.**—The local causes of constipation include: (a) Lesions inducing narrowing of some part of the large intestine, as from cicatrising of an ulcer or displacement of the bowel. (b) Collections of scybala, intestinal concretions, &c., in the cæcum, sigmoid flexure, or rectum. Fæces are more especially apt to collect when too solid or when deficient in bile. (c) Pressure on the rectum, by

uterine fibroids or ovarian tumours, uterine displacements, the gravid uterus, or an enlarged prostate. (d) Defæcation thwarted, as when the expiratory abdominal muscles are enfeebled, as in pregnancy—especially when repeated or after twins, obesity, old age, or in some painful affection of the abdomen, such as rheumatism of the abdominal walls and diaphragm, chronic dysentery, piles, fissure, or the evacuation of a hard mass of fæces. (e) Feeble contraction of the intestinal muscular fibres, as in distension of the large intestine or a portion of it by gas, fæces, or lumbrici, inflammatory affections (chronic intestinal catarrh, chronic peritonitis), lead-poisoning, senile atrophy, or in delicate females with lax muscular fibre (*see COLON, Diseases of*). (f) Pain in the pelvic viscera, and probably elsewhere, may induce paralysis of the sympathetic nerves supplied to the intestinal walls; thus may be explained obstinate constipation in painful uterine and ovarian diseases, which cannot be accounted for by pressure on the bowels or otherwise.

**General.**—The general causes of constipation are: (a) Sluggishness of function—lymphatic temperament, hereditary influence, anæmia, especially with amenorrhœa; or, on the other hand, disposition to great activity of the muscular and nervous system. (b) Certain habits, such as sedentariness; railway travelling—long journeys; too great muscular activity; mental application, especially when excessive or prolonged; the continued and *apparently* necessary use of aperients or enemata after the relief of temporary constipation—falling under the tyranny of aperients; habitual disregard of defæcation, or hurry in the act; prolonged hours of sleep; the excessive or even moderate use of alcohol, tea, tobacco, or opiates. (c) Dietetic errors: the diet too nutritious—leaving little intestinal residue, or poor and insufficient; improper feeding, especially in infants and children; and the use of indigestible substances, such as cheese, nuts, or uncooked vegetables.

Constipation is frequently a prominent symptom in diseases of the stomach; of the liver; of the heart, inducing congestion of the portal system; and of the nervous system: as well as in connexion with diabetes, excessive perspiration, prolonged lactation, and morbid discharges.

The causes of constipation are such as evidently induce one or both of the following conditions, namely, (1) dryness and hardness of the contents of the large intestine from deficient secretion, or too active absorption of fluid from the intestinal tract; and (2) impaired contraction of the muscular fibres of the large intestine.

**DESCRIPTION.**—In constipation the evacuations are infrequent, solid, deficient in quantity, and sometimes unusually offensive; they often consist of dry, hard, dark or clay-

coloured masses or scybala. Defæcation is generally difficult or even painful. As a rule the depth of colour, and the scybalous character of the motions, are in proportion to the duration of the lodgment of fæces in the large intestine. Infrequency of defæcation regarded alone is an untrustworthy sign of constipation, or of constipation demanding medicinal or other treatment, inasmuch as it often depends on individual peculiarity. Good health may be consistent with departures from the ordinary rule—a daily evacuation; not infrequently there is no relief from the bowels for several days or even for a week, and yet without inconvenience, so long as the infrequent defæcation is habitual, or can be ascribed to idiosyncrasy.

The disturbances of function usually associated with constipation may be local, or may extend to distant parts.

The *immediate* or *local* effects are such as may arise from retention of fæces:—signs of fæcal collections in the cæcum, colon, sigmoid flexure, or rectum; irritation of portions of the intestine, indicated by colic, inflammation, dilatation, ulceration, and perforation of the intestines, followed by peritonitis; intestinal obstruction—a portion of the bowel loaded and distended with fæces being no longer capable of peristaltic movement; pressure of fæcal accumulations on the intrapelvic vessels and nerves, inducing menorrhagia, uterine catarrh, seminal emissions, varicocele, hæmorrhoids, cold feet, neuralgia, numbness and even œdema of the legs (*see FÆCES, Retention of*). Constipation frequently exerts a pernicious influence on primary digestion, indicated by foul tongue, fetid breath, anorexia, acidity, flatulence, biliary disturbance—even jaundice, and urine loaded with lithates.

The *remote* or *general* effects of constipation are lassitude of body and mind; headache, flushing, heat of head, and vertigo; palpitation; anæmia, and wasting. Headache and nausea depending on retention of fæces may be either pretty frequent without loaded tongue; or may recur with vomiting and much coating of tongue every three or more weeks—these periodical attacks resembling migraine, but always cleared up by an aperient.

**TREATMENT.**—Constipation depending on individual peculiarity is rarely relieved permanently by treatment. The bowels, having acquired from early life the habit of infrequent evacuation, may be stimulated for a time, and are then apt to become more sluggish than before. In all cases the habit of the patient in this respect from childhood should first be determined, either as a caution against active or prolonged treatment, which may prove injurious, or as a guide to the adjustment of directions and remedies—affording as it does a limit which should not be overstepped. A healthy daily discharge

of fæces should not fall far short of five ounces, and should form a coherent cylindrical-shaped mass of five or six inches in length, which should float; and it is an essential condition of healthy and efficient defæcation that the colon should always be moderately full of retained fæces. The practitioner should bear in mind that many persons acquire the erroneous belief that they are not discharging a sufficiency of fæces, and in consequence betake themselves to aperients, which daily remove the normal residuum of fæces that should exist in the colon—healthy peristalsis and defæcation being thus out of question. This apparent constipation can only be met by completely suspending the use of aperients.

1. *Ætiological, hygienic, and dietetic treatment.*—In treating constipation the causes should be met. Local causes, such as those inducing contraction of or pressure on some part of the large intestine, or feeble or ineffectual contraction of the intestinal muscular fibres or of the expiratory muscles, should first be eliminated. When defæcation is obstructed by the sphincter and either remaining firmly contracted, or failing to relax sufficiently, it may be effectually relieved by forcibly dilating the anus under ether. Habits disposing to constipation should also be corrected. Persons who are much preoccupied or careless are apt either to disregard the call to stool, or to perform the act of defæcation hurriedly, incompletely, and at irregular intervals. Such persons should be strictly enjoined to direct their attention, expectancy, and will to the attainment of complete and regular evacuation. The sensibility of the nerves of the rectum becomes blunted by the constant contact of fæces, and the promptings of nature at last cease. Hence the periodical removal of collections in the lower part of the large intestine is an essential element of the treatment. This is best secured if possible by well-timed and well-directed and sustained natural efforts. The patient should be told to attempt defæcation every day after breakfast, and to persevere in this habit even though the result be occasionally or frequently unsuccessful, and in order to develop his solicitation into the daily habit of evacuation he should continue to practise it always at the same hour, and should disregard any prompting that may arise at other times. While straining to relieve the bowels, he may facilitate evacuation by pressing firmly the fingers in front and on each side of the coccyx, thus supporting the levator ani during contraction, reducing the concavity of the rectal pouch, and causing the mass of fæces to glide forwards through the sphincter, which should be smeared with vaseline; or he may attain the same end by alternately contracting or relaxing the anal sphincter. Failing to obtain relief on the second day,

a small cold-water enema should be used to prevent further accumulation of fæces in the rectum, and to restore tone and sensibility to the blunted nerves. The enema should never be larger than is required to dislodge the motion from the pouch of the rectum, nor should it be warm; at first it may, however, be tepid, but should afterwards be cold. When evacuation is obstructed by the lower part of the fæcal mass becoming dry, relief may be obtained from a small emollient enema administered on rising (such as infusion of linseed, glycerine in small quantities, solution of white of eggs, olive oil alone or in oatmeal gruel) and allowed to remain until after breakfast; or by the use of suppositories at bedtime, consisting of cacao-butter, or honey hardened by heat, either alone or combined with extract of belladonna. The clothing should not constrict the abdomen or waist, and should be warm—especially about the feet and legs. Sedentary habits should be broken into. Exercise on foot or on horseback, or on a cycle, is especially to be commended, and carriage exercise to be avoided. While studying or reading, the patient should walk about, and stand rather than sit at the desk. Gymnastics and out-of-door games (such as lawn-tennis, cricket, football, golf) are useful when a limited time only can be devoted to exercise. Excessive and exhausting exertion should be avoided. It is generally advisable to recommend early rising and cold bathing, followed by brisk general towelling in the morning. In different cases one or other of the following may be found serviceable: a shower or sponge bath containing vinegar or bay-salt, or consisting of sea-water, or a cold sitz-bath; douches directed to the abdomen; a cold-water compress applied to the abdomen during the day or night, or for three or four hours in the morning; friction or kneading, or slapping with the half-closed fist in the course of the colon every morning, and when at stool; an abdominal belt (flannel or elastic)—especially if the abdomen be pendulous.

*Diet.*—The diet should be varied, should not consist too exclusively of animal food, but should contain a good proportion of fresh vegetables, and especially green vegetables (cabbage, lettuce, spinach). Fresh and ripe fruit (such as grapes, apples, and oranges) should also find a prominent place, and are most effective when taken in the early morning, or at breakfast. When fruit induces acidity a tumblerful of alkaline (Vichy or Vals) water should be taken at the same time. Oils and fats are generally serviceable when they do not disturb the digestion, such as the addition of a dessert-spoonful of olive oil to green vegetables or to potatoes. A tea-spoonful of glycerine with each meal is often helpful. The diet should not be too dry. As to beverages, much must be left to individual experience: sometimes coffee, or beer, or cider answers best. A tumblerful of cold water

should be taken night and morning on awaking; sometimes carbonic-acid water in the early morning is found preferable to plain water. Coarse articles of food—such as bran or wheatmeal bread, oatmeal porridge, &c.—are often commended, and now and then they do favour the continuance of more efficient evacuation; more frequently, however, they fail—especially after a time—and they then aggravate the evil by further adding to the undue collection of residue in the large bowel, and are apt to set up catarrhal irritation. Acidity and other symptoms of dyspepsia contra-indicate the use of these indigestible foods. Honey or treacle with bread, gingerbread, and Spanish or Portugal onions, plainly boiled, may be found useful in certain cases. Dujardin-Beaumez recommends infusion of linseed (a little water let stand on a dessert-spoonful of linseed for an hour) immediately before a meal.<sup>1</sup> As a rule, eggs, milk, cheese, farinacea, astringent wines, and tea increase constipation; and besides these articles it is best to avoid pickles, salted meats, nuts, and pastry in any form.

2. *Treatment by massage and electricity.* Many observers in recent years have reported the complete cure of constipation by a course of massage alone. The manipulations consist of kneading (*pétrissage*), stroking (*effleurage*), and slapping (*tapotement*), each having its special effect: the first loosening impacted fæcal masses, the second favouring their passage along the bowel, and the third improving peristaltic action. In some instances the forms of massage best adapted to the case should be applied to the whole of the large bowel from the cæcum onwards; in others it should be addressed specially to certain portions, as the cæcum, transverse colon, or sigmoid flexure. Sometimes all the manipulations, in varying proportions and degrees, are required in succession, or only one or two kinds—for instance, in atony of the bowel depending on sedentary habits, gentle and then deep stroking should give place to strong slapping with the half-closed hand; and in cases marked by flabbiness of the abdominal muscles, the recti should be forcibly separated by the thumbs and fingers, and then strong transverse strokings from the median line should be made, and the patient should take deep inspirations to strengthen the diaphragm. Each case should therefore be treated with discrimination, and a routine method should be avoided. The massage should be applied for from twenty to thirty minutes every or every other morning, and should be continued without interruption for from five to eight weeks.<sup>2</sup> *Electricity,*

<sup>1</sup> *L'Hygiène Alimentaire.*

<sup>2</sup> A rude form of massage has been suggested in the form of a cannon-ball, or other similar round metallic body, weighing 3 or 4 lbs., to be rolled up and down the uncovered abdomen for from five to ten minutes daily at the same hour, the patient being recumbent.

either alone or with massage, has also proved successful in certain cases; a mild galvanic (continuous) current being applied by inserting the negative pole well within the sphincter ani and drawing the positive pole along the colon, and the faradic (interrupted) current being passed through the abdominal muscles.

3. *Medicinal treatment.*—Should the foregoing directions fail to establish the habit of a regular action of the bowels—either daily or on alternate days, they may be supplemented by the prescription of medicinal agents, to compass the twofold aim of (1) relieving the large bowel of the excess of fæces and gases which, by over-distending it, opposes peristalsis, and (2) toning its walls. To this end care should be taken to so adjust the dose (for it varies considerably in different cases) as to secure if possible efficient assistance to the discharge of fæces, without going so far as to clear away or to considerably reduce the normal residuum which should always exist in the colon. If, therefore, any prescribed dose has exceeded this limit it should be reduced, and should not be given next day, but after the lapse of a day or two. Repeated purging exhausts torpid bowels, and perpetuates constipation. Nor should the bowels be pushed to more frequent relief than has been habitual with the patient from early life. If the evacuations habitually contain scybala, and fæces are generally found, on examination, in the rectum, the injection of a tea-spoonful of glycerine, or the insertion of a glycerine suppository, twenty minutes or so before the time of the desired evacuation, may alone suffice, or may enable a smaller dose of medicine to deal effectually with the difficulty. If gentle assistance only is required, and if griping and other signs of irritation are readily set up by the ordinary aperients, one or other of the following may be tried:—a tea-spoonful of castor oil alone, or with an equal part of glycerine, beaten together and then added to a table-spoonful or two of milk, or with olive oil or almond oil, at bedtime or in the early morning; the official sulphur lozenges (suggested by Sir Alfred Garrod) or tabloids at bedtime; rhubarb and dried carbonate of sodium (gr. ij. or iij. of each), or a small piece of rhubarb-root before the midday meal; pills of dried ox-gall and soap. Or, if a more decided laxative is necessary, a preference may be given to the compound liquorice powder, or confection of senna (with or without confection of sulphur or the compound sulphur tabloids), or the infusion of a few senna-pods in half a tumbler of water let stand over night, or extract of cascara sagrada. During late years cascara sagrada has acquired a high position as a tonic aperient, and is prescribed either in the form of solid extract (as in tabloids or pills, alone or variously combined), or in that of the liquid extract—the dose of the latter varying from ℥v. to ℥xxx. alone or asso-

ciated with tincture of nux vomica, of belladonna, or of podophyllum, in a tea-spoonful of glycerine, or along with euonymin in capsules. Combinations on the lines of the favourite formula of Sir Andrew Clark also meet the indications well in the majority of cases (aloin, extract of nux vomica, extract of belladonna, sulphate of iron, powdered myrrh, powdered soap, of each half a grain; and, if the fæces are dry and hard and there is no special weakness of the heart, add powdered ipecacuanha half a grain). Some prefer a pill of Socotrine aloes with henbane and sulphate of iron and quinine. In a well-organised course of medicinal treatment the form of the aperient should be varied every now and then, and the dose very gradually reduced until at last it is almost withdrawn, while the intestinal tonics (belladonna, nux vomica, and iron) should be continued. The time when the dose should be taken is important, for it will vary—be it before lunch, or dinner, or at bedtime—with the slowness or quickness of the response of the bowels to the attainment of relief after breakfast. Bretonneau's treatment by belladonna, greatly prized by Trousseau, is described in the article COLON, Diseases of.

In anæmic cases a firm and prolonged course of iron should be aided by aloes, nux vomica, and arsenic. In hæmorrhoidal complications aloes should, as a rule, be avoided, and laxative electuaries should be prescribed; in some cases, however, it gives tone without irritating the rectum. In obstinate cases colocynth—either alone or variously combined—is most useful; such as the tincture of the Prussian Pharmacopœia, ℥v. or more on sugar or in extract of liquorice (to disguise the bitterness) three or four times a day, or 10 to 20 minims an hour before breakfast; or the extract or compound pill with small doses of croton oil, or with gamboge, elaterium, or other combinations. A full dose of opium may liberate the bowels after the failure of the strongest purgatives, and constipation depending on inhibition of the sympathetic nerve from pain will be relieved by opium with belladonna. When constipation is associated with a deficient flow of bile, chologogues (such as an occasional mercurial, euonymin, or podophyllum) should be prescribed with the other remedies; and dried ox-bile in capsules or pills, and nitric acid or nitro-hydrochloric acid often prove useful. Sometimes enemata answer better than purgatives; then, when frequently required, they should be small in quantity, and at first tepid, afterwards cold; for occasional use, for the purpose of clearing away fæces loading the large bowel, they should be large (from two to six pints) and warm (*see* FÆCES, Retention of). The frequent use of large warm injections perpetuates constipation. Purgative waters, such as the Rubinat, Friedrichshall, Pullna, Hunyadi János, or Carlsbad, given in warm water

in the early morning or over night, are often valuable adjuncts to other treatment. A combination of the sulphates of iron, magnesium, and sodium with strychnine and belladonna, after food twice a day, is often efficacious; especially in the constipation of children; and in children under two years of age carbonate of magnesium (gr. v. to xx.) in milk is preferable to other aperients.

GEORGE OLIVER.

**CONSTITUTION.**—SYNON.: Diathesis; Habit; Conformation of Body; Fr. *Constitution*; Ger. *Leibesbeschaffenheit*.

The constitution may be sound or unsound. A sound constitution may be defined as the harmonious development and maintenance of the tissues and organs of which the body is made up. It originates with the union of a healthy sperm and germ cell, continues with the growth of the product under the most favourable conditions to adult life, and becomes gradually enfeebled with advancing age by the process of natural decay.

The constitution may be unsound in consequence of *deficient vitality*. This deficient vitality may be general, as is sometimes observed in the children of parents one or both of whom are in advanced life, or whose vitality on one side or the other has been reduced by excesses, such as alcoholic or venereal. Exhausted vitality from prolonged disease, e.g. phthisis or tertiary syphilis, affecting either parent, may determine the death of the offspring at an early period, from mere failure of nutrition, or may cause it to succumb to acute disease not necessarily associated with any inherited tendency of a special kind. The deficient vitality may be restricted to certain tissues or organs, namely, those concerned in the nervous, vascular, respiratory, or digestive systems. Thus amongst the most strikingly hereditary of diseases are those of degeneracy, such as emphysema, structural heart-diseases, atheroma of vessels, and certain kidney-diseases. Rightly interpreted, these diseases are of the nature of premature senility, attacking certain tissues or organs—as it may be seen to attack the hair or the cornea—from some inherent defect in their vitality.

The constitution may, in the second place, be unsound from some definite *inherited* form of disease. Although the constitution of an individual begins with his life, it is nevertheless the resultant of the constitutional peculiarities of many antecedents. This being so, tendencies to disease may date far back in the pedigree, to be called forth from time to time by favouring circumstances. We need, however, practically only go back a few generations in inquiring for those diseases which are well recognised as being hereditary. These form one section of the group of *constitutional diseases*.—Congenital syphilis, gout, scrofula, tuberculosis, cancer, asthma, and certain neuroses, are all diseases which

are apt to appear at certain periods of the life of the offspring, in consequence of some specific inherent defect of blood or tissue derived from his progenitors.

The constitution may, thirdly, become unsound at any period *subsequent to birth*. (a) This may be due to the surrounding conditions of life being evil. Deficient or impure air, insufficient or improper food, defective sunlight, over-work, intemperance, &c., may injure the constitution, and give rise to diseases whose constitutional nature is sometimes strikingly shown in the tendency of some of them to become hereditary. Rickets, phthisis, and scrofula are examples. (b) The introduction of certain poisons into the system affects the constitution profoundly, and in some cases permanently, after the more obvious effects of the poisons have passed away. All the acute specific zymotic diseases, including vaccinia, would come under this category. They render the organism, for a long period or for life, proof against subsequent attacks of the same disease. Only in certain cases, however, can the soundness of the constitution be said to be *impaired* by such diseases, and then it is usually through the occurrence of sequelæ.

R. DOUGLAS POWELL.

#### CONSTITUTIONAL DISEASES.

These may be regarded as diseases generated from within, in the course of the wear and tear, nutrition and waste, of the body, in consequence of inherent or acquired weakness in its construction.

The applicability of the term 'constitutional' to disease is sufficiently explained in the preceding article on CONSTITUTION. The term may, however, be associated with a group of so-called 'general' diseases, in opposition to that which includes 'zymotic' or 'specific' diseases, which are generated by the introduction of some definite poison from without.

In our present state of knowledge, however, no very rigid lines can be drawn to separate local, general, constitutional, and specific diseases from one another. See DISEASE, Causes of.

R. DOUGLAS POWELL.

**CONSTRICION** (*constringo*, I bind together).—A narrowing, to a limited extent, of a canal or hollow organ, due either to a textural change in its walls, or to the pressure of a band surrounding it.

**CONSUMPTION** (*consumo*, I waste).—A term for any wasting disease, but generally applied to pulmonary phthisis. See PHTHISIS.

**CONTAGION.**—The word *contagion* is applied in pathology to the property and process by which, in certain sorts of disease, the affected body or part causes a disease like its own to arise in other bodies or other parts; and the Latin word *contagium* is conveniently

used to denote in each such case the specific material, shown or presumed, in which the infective power ultimately resides. See ZYME; and ZYMOSES.

The property of CONTAGIOUSNESS belongs to a very large number of the diseases which affect the *human* body. And in more than this direct way the property is of great interest to mankind. Contagiousness of disease is a fact not only for man, but apparently for all living nature; and the influence of contagion in spreading destructive diseases among *domestic animals*, and among those parts of the *vegetable kingdom* which contribute to the nourishment of man, is such as to make it of immense social importance that the laws of contagion should be well studied and understood. Further, just as contagion in the case of *living* bodies and their parts spreads disease from one to another, so, to an immense extent, in the case of certain matters which, though of organic origin, are *not living*, it spreads various processes of decay. The so-called 'fermentations' which yield alcohol and vinegar, as well as that in which putrefaction consists, are contagious affections of the respective matters in which they occur: every cheesemonger knows that moulds of different kinds spread by inoculation, each in its own kind, from cheese to cheese; and if the Greek proverb 'grape mellows to grape' is true of the living fruit, the apple-loft gives analogous experiences of contagion among the fruit which is garnered.

The RATIONALE of the word 'contagion' as now used, is that the property is understood to attach itself essentially to a material *contact*; not necessarily that, when infection is spread from individual to individual, the contact of the individuals must have been *immediate*; but that in all cases there must have been such passage of material from the one to the other, as was in itself at least a *mediate contact* between them. And similarly, in those very instructive illustrations of the process of contagion which are furnished within the limits of a single diseased body by the propagations of disease from part to part of it, we can in general easily see that infection advances from part to part, either in proportion as part touches part, or in proportion as the one receives from the other the outflow of lymph or blood or secretion.

The various SPECIFIC MATTERS which effect contagion in the living body, the respective 'contagia' of the given diseases, seem all to have in common this one characteristic: that in appropriate media (among which must evidently be counted any living bodily texture or fluid which they can infect) they show themselves capable of *self-multiplication*; and it is in virtue of this property that, although at the moment of their entering the body they in general do not attract notice, either as objects of sense or as causes of

bodily change, they gradually get to be recognisable in both of these respects. Now, the faculty of self-multiplication is eminently one of the characters which we call *vital*; and when it is said that all contagia are self-multiplying things, this is at least very strongly to suggest that perhaps all contagia are things endowed with life.

In order to any general consideration of the question thus suggested, contagia may conveniently (even if but provisionally) be distinguished as of two main CLASSES, differing, or at present seeming to differ, from each other in their mode of action on the organisms which they infect: one class, namely, that of *Parasites*; and the other class, that of the true or *Metabolic Contagia*. Of this separation, so far as present knowledge seems to justify it, the assumed grounds are: that each true Contagium, in proportion as it multiplies in the body, *transforms*, in a way which is specific to itself, and is different from the ways of other contagia, the bodily material with which it has contact; while, on the contrary, the Parasite, however much it may grow or multiply in the body, produces no qualitative effects specific to itself, but only such effects as are of common kind to it and all other parasites—indications, namely, of its *mechanical intrusiveness* in the parts which it occupies, and sometimes of the *drain* which it makes on its host's general nutritive resources.

A.—Of PARASITES, in relation to processes of contagion, little needs be said in the present article. When an organism or part of it is, in greater or less amount, inhabited by other organisms, animal or vegetable, which subsist on it, or its food or refuse, it of course may be a centre of infection to other (if susceptible) bodies or parts, to which it can transmit live parasites or their germs or seeds: for, when this transmission takes place, growth and self-multiplication, as in a colony, are the natural results which have to be expected; and in proportion as these occur, the newly-infected body or part gradually gets to suffer, like the old, from those particular derangements which make the type of parasitic disease. Some parasitic diseases, especially some of those of the skin, spread actively by direct contagion in ordinary intercourse; as, for instance, scabies by the migration of its acari, and porrigo (among children) by the spores of its microphyte; and the spreading of such diseases where they exist may of course be to any extent facilitated by aggregation of persons and uncleanliness of personal habits. There are cases in which parasitic disease spreads from animal to animal only in proportion as the one feeds on the other, and eats it with parasites still living in it; or in proportion as live parasite-eggs or larvae, discharged from the body of one animal, get conveyed with food

(especially on raw herbage and in water) into the bowels of another. Considerable epidemics of trichiniasis in the human subject have been traced, chiefly in Germany, to infection from the pig; in cases where pork, abounding with trichinæ, has been eaten, as sausage-meat or otherwise, in a raw or imperfectly-cooked state: and in Iceland the very great sufferings of the human subject and the cattle from echinococcus have been traced to the influence of the dogs in spreading contagion from the slaughter-house, where they eat hydatidised offal, to the kitchen-gardens and water-sources and pastures, where they discharge tape-worm eggs from their bowels. *See* PORRIGO; SCABIES; ENTOZOA.

The DISEASED STATES which consist in being colonised by parasites are diseases of indefinite duration, tending in some cases to indefinite increase. In cases where the disease consists in the presence of swarms of blood-sucking or otherwise exhausting animal parasites, symptoms of the blood-drain will of course gradually arise; but otherwise the parasite, whether animal or vegetable, operates only as a mechanical presence. Skin and mucous membrane will be irritated in their superficial layers, and in some cases more deeply, by the animal or vegetable parasites which breed on or in them, just as they might be by dead mechanical irritants: solid organs having cystic entozoa in them will in like manner show evidence of irritation by encapsulating the colonists; and the surrounding tissue will of course suffer compression and displacement in proportion as the colonisation (*e.g.* in case of echinococcus) is compact and massive. In the case of trichiniasis—but, in our ordinary experience, in no other—the multiplication of the parasites, the burrowing of their young, and the general diffusion of these in the body, are processes of such extreme activity that, if the quantity of contagium taken into the stomach has been large, the innumerable local irritations suffice to make a very acute fever; but even in this extreme case, the merely irritative type, though exaggerated, is essentially preserved.

As different sorts of animals are notoriously liable to different sorts of parasites, so, even among animals of one sort—as, for instance, in the human kind—the LIABILITY of different bodies to receive particular parasite-infections, does not seem to be quite equal for all. Especially, the vegetable parasites seem to have their affinities determined or modified by the general state of health of the recipient; and there are cases in which it looks as if there ran in particular family-lines (perhaps with some slight chemical idiosyncrasy) a special liability to particular intestinal worms. There, however, is no reason to believe that in regard of the more important animal parasites, as particularly of

trichina and the tæniadæ, the susceptibility of individuals to attacks is other than universal and practically equal.

B.—The true or METABOLIC CONTAGIA (to which the rest of the present article will exclusively refer)—the contagia which, in their respective and specific ways, operate *transformingly* on the live bodily material which they affect, are perhaps the most important of all the incidental physical influences which concern mankind. Whether they may all, at some time hereafter, admit of being named, like the parasitic contagia, in terms of biological classification, is a question which needs not in the first instance be raised; for meanwhile the identity of each separate true contagium is settled in experimental and clinical observation by the uniformity of the operation of each on any given animal body which it affects. Each of the diseases propagates itself in its own form in as exact identity as if it were a species in zoology or botany; and in each such repetition of the disease there is a multiplication—always a large, and sometimes an inconceivably immense multiplication—of material which has the same infective property. Evidences innumerable to that effect are under daily clinical observation in this climate in instances of smallpox, measles, scarlatina, whooping-cough, enteric fever, mumps, typhus, syphilis, cowpox, diphtheria, erysipelas, hospital gangrene, purulent ophthalmia and gonorrhœa, venereal soft-chancere and phagedæna, &c.; for, barring fallacies, no man ever sees any one of those diseases produced by the contagium of any other of them; and any man who has before him a case of any of them can see that, however minute may have been the quantity of contagium by which the disease was started, the patient's diseased body (part or whole) yields for the time an indefinitely large supply of the specific agent. It is more or less habitual to some of the diseases that the infectedness of the patient is first made known to the observer by such *general pyrexia* as tells of change already far advanced in the circulating mass of blood; and it is only after this has shown itself, that other symptoms, adding themselves to the fever, complete the more or less complex type which establishes the identity of the disease. But in many of the diseases it may be the case (either naturally or as the result of experimental infection) that the first, and in some diseases the main or even the only, effects of the contagion are *local changes*, passing where we can from the first observe them; and the broad facts of metabolic infection, as regards waste of bodily material with concurrent increase of contagium, are, in many such cases, among our most familiar experiences. Most instructive, too, are the facts of contagion which are to be learnt in the study of tubercle: the contagium, introducible either by tubercular and

certain septic inoculations through the skin, or internally by the infective action of the milk or diseased organs of tubercular animals if taken as food; and the contagium, when introduced, gradually spreading as it multiplies, and as lymph and blood carry it from the first infection-spot to other organs which now will repeat the process. And similarly in cancer (though the primary disease is at present of unknown origin and cannot be created by experiment) the repetition of the primary disease in secondary and tertiary propagations in the body of the sufferer is one of the most striking of all evidences of contagion; because of the great number of structural types which pass under the name of cancer, and the fidelity with which each of them is reproduced in the organ to which the contagion extends. A further fact of contagion, deserving notice in the present context, is the local spread of certain of these processes by continuity of tissue; as, for instance, in the continuous extension of phagedæna or hospital-gangrene from any centre of first inoculation, or of tubercular softening or cancer at the place where it begins: a mode of extension which indicates successive infective actions of matter on matter in spheres of ever-widening circumference;<sup>1</sup> and the like of which, but in rudimentary degree, may be traced in the areola of any acute inflammation.

In the physiology of the metabolic contagia no facts are more characteristic or more important than those which show the RELATIVENESS of particular contagia to PARTICULAR RECEPTIVITIES of body.—First, and in intimate connexion, as would seem, with a *chemical electiveness* of action which will presently be imputed to contagia, there is the preference which some particular contagia (however introduced into the system) show for particular *organs* of the body; so that by the exercise of this preference, there is given to each of the diseases its own set of clinical and anatomical characters. Compare, as instances in this point of view, the respective local affinities of smallpox, enteric fever, mumps, syphilis, hydrophobia, &c.—Secondly, it may be noted that, in regard to some of the contagia, different *persons*, and particularly persons of different *family-stocks*, show original differences of susceptibility; original, namely, as distinguished from others, hereafter to be mentioned, which are acquired; so that, for instance, the severity with which scarlatina or diphtheria will strike in particular families contrasts with a comparative mildness of the same disease in other families, or perhaps even with cases of apparently complete personal immunity under exposure to the particular danger: and recent researches have seemed to suggest as possible that, in the

very wide differences of degree with which tubercular disease prevails in different families, an essential condition may be, that the families have widely different degrees of original predisposition towards some of the septic contagia.—Thirdly, there is the extremely suggestive fact with regard to many of our best-known febrilising contagia, that they run a course of *definite duration*, and that in this course, provided the patient do not die, all present, perhaps all future, *susceptibility to the particular contagium is utterly exhausted from the patient*; so that re-introduction of the same contagium will no more renew that patient's disease than yeast will excite a new alcoholic fermentation in any previously well-fermented bread or wine. The inference from this fact seems unavoidable, that each such contagium operates with a chemical distinctiveness of elective affinity on some special ingredient or ingredients of the body; and that exhausting this particular material in febrile process, which necessarily ends when the exhaustion is complete, is the bodily change which the contagium 'specifically' performs.—Of not all metabolic contagia, however, can it be said that their operation runs so definite and self-completing a course. For, first, there are particular *acute infections* which, as a rule, kill; either (as appears to be the case in splenic fever when affecting man) because of the extreme magnitude of the transforming process which the contagium sets up, or else (as appears to be the case in hydrophobia) because the elective incidence of the contagium is on an organ indispensable to life; so that in such cases there is in fact hardly such an event as passing alive through the whole process of the disease. And, secondly, there are the *contagious dyscrasies* which are clearly characterised by their tendency to indefinite duration: syphilis, which oftener than not relapses in successive outbreaks, and often as years pass invades the body more and more deeply, and may after all never during life be ended; and tubercle and cancer, which, with almost invariable persistence, will in general steadily advance month by month to infect more and more of the body till the process eventuates in death.

The transmission of various contagious diseases IN COMMUNITIES is of course greatly influenced, both in detail and in aggregate, by such differences of individual receptivity as were mentioned in the last section. Notably, as regards communities through which particular acute infections have had full run, fresh sparks of the contagium may find little or no fuel on which to act; and much new diffusion of the disease may not again be possible, till immigration, or births, or lapse of time operating in other ways, shall have reconstituted a susceptible population. And, given the susceptible population,

<sup>1</sup> Compare Tennyson's

'little pitted speck in garnered fruit,  
Which, rotting inward, slowly moulders all.'

circumstances of time and place are infinitely various (especially as regards quantity and quickness of personal or quasi-personal intercourse) in determining how far this population shall have particular contagia thrown in its way.

Also there are conditions, not primarily of a personal kind, which operate on a very large scale in determining the spread of some of the metabolic infections: giving to them respectively *at certain times*, in ways not hitherto understood, a *special increment of spreading-power*, and in some instances also *special malignity*: and thus enabling them respectively from time to time to come into comparative prominence in national life, and perhaps at once or successively in many different countries, in the form of so-called EPIDEMICS. Thus, it is matter of familiar knowledge that the fevers which are most habitual to this country—scarlatina, measles, smallpox, enteric fever—are of nothing like uniform prevalence; that scarlatina, for instance, will be three times as fatal in one year as in another, and that smallpox is liable to even greater exacerbations: and it is known that temporary differences of this kind are not exclusively local; that, for instance (to quote a late official report), ‘the epidemic of smallpox which began in England towards the close of 1870 and terminated in the second quarter of 1873 was part of a general epidemic outbreak of that disease, of worldwide diffusion, marked wherever it occurred by an intensity and malignity unequalled by any previous epidemic of the disease within living memory.’ The wider the survey which we take of epidemiology, the more certain it becomes to us, that, outside the conditions which are independently personal or local, there are *cosmical conditions* which have to be considered. Doubtless there are great epidemiological facts—such, for instance, as the first spreading of smallpox to America, or in our own times the increasing frequency of Asiatic cholera in Europe, which may be ascribed to novel conditions of international intercourse; but there are others, equally great, to which apparently no such explanation can be applied. For what reason it is that cholera every few years has its definite fit of extension in India,—or why diphtheria, which scarcely had a place in history till it overran Europe in the 16th century, and which since then had been rarely spoken of, began again some twenty-odd years ago to be comparatively important in England,—or why the plague of the Levant has for the last two centuries been so unfamiliar to us,—or why the yellow fever of the Mississippi has in particular years raged furiously in parts of Europe,—or why our black-death of the 14th century, though apparently still surviving in India, has never but that once been in Europe,—or whither has gone our sweating-sickness of three centuries ago,—or whence have

come the modern epidemics of cerebro-spinal meningitis: these, and many like questions, which cannot at present be answered, seem to be evidence enough that, in the making of epidemics, contagion and personal susceptibility may be factors in a partly *conditional* sense. Influences which are called ‘atmospheric’—the various direct and indirect influences which attach to the normal succession and occasional abnormality of seasons, in respect of the insolation of our planet, and of the temperature and humidity of air and earth—are in general far too vaguely regarded as elements of interest in the present question, but are possible factors which no epidemiologist should omit from scientific consideration. For any definite knowledge which exists on the relation of particular conditions of season to the prevalence of particular epidemics, the reader is referred to the article EPIDEMICS, and to articles on the respective diseases.

In the PASSAGE of the metabolic contagia FROM PERSON TO PERSON various agencies may be instrumental,—bedding or clothing or towels which have been used by the sick, dirty hands, dirty instruments or other utensils, the washerwoman’s basket, foul water-supply, stinking house-drains, contaminated milk or other food, the common atmosphere, &c.; but differences of that sort are only differences as to the *means by which such communication is established with a diseased body* as brings its products into relation with healthy persons; and the disengagement of *infectious products* from the bodies of the sick is pathologically the one influential fact. As regards the products which ought to be deemed infectious, the specially-diseased surfaces and organs of the patient, and the discharges and exhalations which they respectively yield, must always be regarded with chief suspicion; but suspicion, however much it may insist on them, must never disregard other sources of danger. Of some of the metabolic contagia we practically know, and of many of the others we may by analogy feel sure, that, when a given body is possessed by one of them, no product of that body can be warranted as safe not to convey the infection. Presumption against every part and product of the diseased body is by everyone readily admitted where there are vehement general symptoms of disease: but it is important to know that not only in such febrile states, but even in states of chronic dyscrasy, and even at times when the dyscrasy may be giving no strong outward sign, the infected body may be variously infective. Thus, in regard to constitutional syphilis, it is certain that the mere utero-catarrhal discharge of the syphilitic woman, or the sperm of the syphilitic man, or the vaccine lymph of the syphilitic infant, may possibly contain the syphilitic contagium in full vigour, even at moments when the patient, who thus

shows himself infective, has not on his own person any prominent outward activity of syphilis. Similarly, in regard to tubercular disease, experiment has proved beyond question that the milk of animals suffering from tubercle will, if taken as food by other animals, infect them through the intestinal mucous membrane; and there are independent reasons for believing that the tubercular contagium (like the syphilitic) will at times during the dyscrasy be contained in the seminal fluid, and that men, tubercular perhaps only in some degree which is not immediately important to themselves, may by that secretion convey fatal infection to women with whom they have conjugal relations.<sup>1</sup> Regarding many of the metabolic contagia, conclusive evidence exists that, when they are in operation in pregnant women, the fetus will in general be infected by them; and this though the diseases (*e.g.* smallpox, cholera, syphilis) be of the most different pathological types: but with regard to pregnant animals affected with splenic fever it is noticeable that Brauell, in his extensive researches, found the blood of the fœtus not to be infective.

In general, each contagium has its own favourite WAY OR WAYS OF ENTERING THE BODY; and these preferences are not only of speculative interest, as attaching to varieties of nature and natural habits among the contagia, but are of obvious practical importance as measures of the widely different degrees in which the different contagia are qualified to spread in communities. Thus, *inoculation at broken surfaces* of skin or mucous membrane has long been known as the ordinary mode by which the infections of syphilis, hydrophobia, splenic fever, cowpox, and farcy or glanders, get admission to the body; and our best knowledge of some other infectious diseases (notably of tubercle) has been derived from inoculations intentionally made with their contagia for purposes of study. While probably all infections which tend to be of general action on the body can be brought into action in that way, and while some infections are not known to pass by any other mode of transmission, there are many infections which spread freely from subject to subject by *atmospheric and dietetic communication*; and the meaning of these preferences is hitherto not fully known. It seems that some contagia are so acted upon by air and water, that they seldom or never reach the body in an effective state by those common means of communication,—some hardly, if at all, by water, and some not by air except with very close intercourse; and further, that, of contagia which reach the body in an effective state, some require, while others do not require, that an abnormal breach of surface shall give them special opportunity for taking hold. In some of the cases where a disease

can be propagated in both ways,—*i.e.* certainly in smallpox, and apparently also in bovine pleuro-pneumonia, the artificially inoculated disease tends to be much milder than the disease otherwise contracted; but pathologically it is difficult to conceive any essential difference between those different modes of contagion. It may be presumed that, in the modes which are not by true inoculation, acts which are comparable to inoculation take place on internal surfaces; that, for instance, when particles of scarlatina-contagium are caught in the tonsils, or inhaled into the bronchi, or swallowed into the stomach, they begin by penetrating the texture of the mucous membrane, and by thus effecting as real an inoculation, with regard to the blood, as that which art or accident provides in other cases through the punctured skin. That previous abnormal breach of surface by artificial puncture or otherwise is not necessary to allow the infection of mucous surfaces is illustrated in ophthalmia and gonorrhœa; where apparently no other condition has to be fulfilled than that a particle of the blenorrhagic contagium shall be deposited on the natural surface of the mucous membrane. It deserves notice that, while a considerable number of the worst diseases of the domestic animals admit of being communicated to man by artificial inoculation, atmospheric communication seems to be very inapt, if not absolutely unable, to infect man with any one of them; and in this connexion it may be of interest to remember that syphilis, one of the most familiar of human infections, but hitherto not traced to any brute ancestry, differs from our other current infections in requiring inoculation to transmit it.

When any metabolic contagium enters the animal body, it requires an INTERVAL OF TIME, and in most cases a considerable interval, before its morbid effects can become manifest even to skilled observation. The period of latency or so-called INCUBATION varies greatly in different cases. In hydrophobia it is very rarely less than of one month, is certainly often of several months, and is said to be sometimes of years. In syphilis the inoculated spot remains generally for at least a fortnight, and may remain even as much as five weeks, without any ostensible change; and the roseola of the general infection will not be seen till some weeks later, when generally at least three months will have elapsed since the first inoculation. In the acute eruptive fevers, when their contagium is transmitted by air, the first changes which ensue on infection are not external, and we cannot be sure what early internal changes may take place; but in smallpox, the fever (which is the first overt sign) does not attract notice till about the twelfth day after infection, nor the eruption till two days later; and in measles the incubation-time, though per-

<sup>1</sup> See Dr. Weber, in *Clin. Soc. Trans.*, 1874.

haps less uniform, seems to be little (if any) shorter than that of smallpox. The septic contagia and the contagium of splenic fever seem to be of particularly quick operation; but even the most virulent septic contagium, when without admixtures which tend to complicate its action, will not begin sensibly to derange the infected animal till at least several hours after it has been inoculated. As regards the contagia last referred to, it is conceivable that the self-multiplication of the contagium in the form in which it proves fatal to life is a process which goes on continuously and uniformly from the moment of inoculation to the moment of death, and that the moment when signs of general derangement become manifest is the moment when this uniformly-advancing process has accumulated in the system a certain quantity of result:—but it does not seem easy to apply this explanation to the diseases of long incubatory period; and we can hardly conjecture what may be the latent processes—for instance of smallpox, during the first ten or more days after contagium has been received.

It is not yet possible to say, in any universal sense, with regard to the metabolic contagia, what is the ESSENTIAL CONSTITUTION of 'contagious matter,' or what the INTIMATE NATURE of the 'transforming power' which the particle of such matter exercises on the particles which it infects.—As regards the question of the FORCE, chemists, when they refer in general terms to the various acts which they designate *acts of fermentation*, allege that certain processes of change in certain sorts of organic matter induce characteristic changes in certain other sorts of organic matter, not by the common chemical way of double decomposition with reciprocally new combinations, but (so to speak) as a mere by-play or collateral vibration-effect of the chemical force which is in movement; and though language can hardly be more vague than this for any scientific purpose, it expresses clearly enough the conviction of experts that a certain great force in nature lies beyond their power even of definite nomenclature, much more of exact identification and measurement. In that most interesting, but most difficult and hitherto almost uninvestigated, branch of chemical dynamics, we are supposed to have our nearest clue to the scientific problems of the present subject-matter. It may be conceded that the 'contact-influences' which are dimly recognised as causing the fermentary changes of dead organic matter have apparent analogues in many of the morbid influences of contagion: for the changes which chemists call 'fermentary' are all catalytic or disintegrative of the organic compounds which they affect; and when living protoplasm is brought by contagion into processes of *characteristic decay*, the analogy seems sufficiently close to justify the word *zymotic* in the naming of the nature of the process. But it must not

be forgotten that, among immediate effects of contagion in the living body, are cases wherein the process (so far as we can yet see) is primarily not *catalytic* or *dis-integrative*, but, on the contrary, *anaplastic* or *con-structive*. Thus, when tubercle gives rise to tubercle, whether by secondary or tertiary infection in a single diseased body, or by infection from the sick to the healthy, each new tubercle which the contagion brings into being is a *growth-product* of the texture which bears it. And similarly, when the innumerable varieties of cancerous tumour propagate themselves by contagion, each after its special type, in the bodies of the respective sufferers, it is growth, not disintegration, which we first see. It would seem that in those cases of anaplastic 'contact-influence' something far beyond the analogy of chemical fermentations must be involved; and, in view of some of them, the physiologist has to bethink himself of the analogy of that 'contact-influence' which becomes the mainspring of all normal growth and development, when the ovum receives spermatric impregnation.—As regards the ultimate ORGANIC CONSTITUTION of the several metabolic contagia—(each of them of course abstracted from accidental admixtures, and seen or conceived in the smallest and simplest units of quantity and quality in which its specific force can be embodied)—modern research seems more and more tending to show that the true unit of each metabolic contagium must either be, or must essentially include, a *specific living organism, able to multiply its kind*. For with regard to those other contagia (as we may properly call them) which spread fermentary processes in common external nature, and of which it is as clear as of the morbid contagia that they multiply themselves in proportion as they act, it seems to be established beyond reasonable doubt that the 'self-multiplication' of each of them as it acts is the self-multiplication of a specific microphyte; and that, directly or indirectly, the microphyte's self-multiplying life is the force which originates the fermentation.<sup>1</sup> This being the case in regard of those fermentations (and the more intimate nature of the process needs not just

<sup>1</sup> In regard of some of these common-world ferments, it seems pretty certain that their characteristic microphytes operate *mediately*—that is to say, by means of special zymotic matters which they respectively produce, and which when produced can be mechanically separated from them: but whether this be true of all the same class of agencies does not hitherto seem fully settled. So far as it may prove to be true for them, that the microphyte is not itself the ferment, but is the producer and evolver of the ferment, the case of these ferments would be in parallelism with that of the chylipoietic and other functional ferments which more highly organised creatures produce for the purposes of their own economy. In the latter case the distinction between the ferment-yielding live bodies (say certain gastric cells) and their not-live product (say pepsin) is already familiar.

here be discussed), it seems probable that the same is in substance true of the specific morbid changes which extrinsic contagia produce in the materials of the living body—probable, namely, that low, self-multiplying organic forms, specific in each case for the particular disease which is in question, are essential to each morbid poison; that the increase of each contagium as it acts is the characteristic self-multiplication of a *living thing*; and that *this* (however obscure may yet remain its mode of operation) is the *essential originator of change* in the affected materials of the diseased body. The fact that low organic forms of the sorts now spoken of have often, or generally, been seen in the morbid products and tissues of persons with zymotic disease, would not by itself be a proof, or nearly a proof, that the forms are causative of the morbid change: for obviously they might be mere attendants on the necrosis and decomposition of bodily material, availing themselves of the process (just as certain insects would) to feed and multiply: and in many of the cases in which micrococci have been seen in morbid material, no direct proof could be given that the meaning of their presence was more than that. There are, however, some cases in which this proof has been completely established; and though such cases are at present but few, the significance of each of them in aid of the interpretation of other cases is of the highest importance. The researches of successive able observers in regard of the splenic fever of farm-stock, and those of Dr. Klein in regard of the 'pneumo-enteritis' (as he names it) of swine, have shown that in each of these cases the microphyte which attends the disease is botanically specific; that it and its progeny can be conducted through a series of artificial cultivations apart from the animal body; and that germs thus remotely descended from a first contagium will, if living animals be inoculated with them, breed in these animals the specific disease. It is equally well known that the organisms (spirilla) which are found multiplying in the blood during the accesses of relapsing fever are botanically specific: but in regard to this disease, experimental proof has not hitherto been given that the spirilla, if separately inoculated, will infect with relapsing fever. Studies as complete as those which have been made in splenic fever and pneumo-enteritis will no doubt sooner or later be made in regard to many other of the diseases, but their progress will necessarily be slow; partly because the objects which have to be scrutinised, and to which specific characters have to be assigned, are so extremely minute, and often so similar among themselves, that none but very skilled and very patient microscopical observers are competent to pronounce on them; and partly again because the conditions of the case are such as to limit very closely the field within

which the essential experimental observations can be made. Meanwhile, however, the two diseases, regarding which the larger knowledge has been obtained, must be regarded as highly suggestive in regard of other diseases of the same pathological group, and particularly as giving importance to fragments of evidence (not by themselves conclusive) which have been gathered of late years in studies of some of these other diseases. Eminently this is true of the large family of the septic infections—including, on the one hand, erysipelas and pyæmia with its congeners, and having, on the other hand, tuberculosis intimately associated with it; and almost equally it is true of enteric fever and cholera and diphtheria, and of the smallpox of man and beast. Thus, though it would be at least premature to say of these diseases that they certainly have as their contagia *microphytes respectively specific* to them, it seems at present not too much to say that probably such will be found the case; and if as much may not yet be said of many other diseases which are due to metabolic contagia, it must be remembered that the right lines of study relating to contagia in this point of view have not till within very recent times been opened. See Postscript, 1.

Of the NATURAL HISTORY of the contagia, considered independently of the part which they play in the living body, there are hitherto only the beginnings of knowledge. The absolutely first origin of contagia may perhaps not be more within reach of scientific research than the absolutely first origin of dog or cat; but their nearer antecedents—the states out of which they come when first about to act on the living body, and generally the variations which they and the common ferments exhibit under natural and artificial changes of circumstance, are within easy reach of investigation; and those humbler studies are likely to give very useful results. For some of our cases we seem to have an instructive analogy in the facts which Professor Mosler has put together in explanation of the blue-milk contagium of dairies—facts showing that the omnipresent penicillium glaucum, if its spores happen to alight in particular (morbid) sorts of milk, will operate distinctively on their casein as an anilin-making ferment, rendering the milk blue and poisonous, and imparting to each drop of it the power to infect with a like zymosis any normal milk to which it may be added.<sup>1</sup> In our own more special field, pathologists have already learnt that certain of the so-called 'morbid poisons'—the contagia of erysipelas, pyæmia, and tuberculosis, are intimately related to the common ferment or ferments of *putrefaction*; and that the most vehement of these contagia can be developed by the artificial culture of successive transmissions in the living body from the comparatively mild

<sup>1</sup> Virch. Arch., vol. xliii

contagium of any *common inflammatory* process.<sup>1</sup>

Two other directions suggest themselves as likely to lead to fields of useful observation and experiment. On the one hand, in *comparative pathology*, and with the tracing of contagion from animal to animal, there is the possibility that at last some lower and relatively worthless order of animals may be found the starting-ground of fatal infections for higher orders; and this, perhaps, by contagia which in their former relations are of mere inflammatory significance. On the other hand, in *geographical pathology*, and with the tracing of contagion from place to place, local centres of contagium-origination may possibly be found, in which the contagium, before it enters the animal body, will show itself an independent microphyte of the earth, first operating on the animal body as the essential force in a local malaria. Some of the worst pestilences known to the human race—yellow fever, cholera, perhaps plague, and also some of the diseases of cattle, have in their history facts which suggest that sort of interpretation: the supposition, namely, that certain microphytes are capable of thriving equally (though perhaps in different forms) either without or within the animal body; now fructifying in soil or water of appropriate quality, and now the self-multiplying contagium of a bodily disease. In regard to our own common ague-poison there seems every reason to suspect that its relation to soil is that of a microphyte; and though we know ague only as practically a non-contagious disease, we do not know that any little transfusion of blood from sick to healthy would not show it to be (in that way) communicable from person to person. See Postscript, 2.

It needs hardly be said that exact scientific knowledge of the contagia, and of their respective modes of operation, is of supreme importance to the PREVENTION OF DISEASE. With even such knowledge of them as already exists, diseases which have in past times been most murderous of mankind and the domestic animals can, if the knowledge be duly applied, be kept comparatively, or absolutely, in subjection; and the fact that at the present time fully a fifth part of the annual mortality of the population of England is due to epidemics of contagious disease is only because of the very imperfect application hitherto made of that knowledge. In the present article it is not necessary to state in detail the practice which ought to be adopted in the various different cases of infectious disease; but

<sup>1</sup> See particularly Professor Sanderson's papers in successive yearly volumes of *Reports of the Medical Officer of the Privy Council* from 1868 to 1877. It concerns the second fact mentioned in the text to remember that apparently every 'common inflammatory process' includes more or less of textural changes which are necrotic and of septic tendency. See *Holmes's System of Surgery*, first edition, article 'Inflammation.'

briefly it may be said that one principle is at the root of all such practice, whatever the disease to which it relates. This principle, which of course becomes more and more important in proportion as the infection is dangerous, and as the persons whom it would endanger are many, is the principle of *thoroughly effective separation* between the sick and the healthy: a separation which, so far as the nature of the disease requires, must regard not only the personal presence of the sick, but equally all the various ways, direct and indirect, by which infective matters from that presence may pass into operation on others. Especially as regards the diseases which make serious epidemics, the principle of isolation is not carried into effect unless due care be taken to thoroughly disinfect in detail all infective discharges from the sick, and all clothing and bedding and towels and like things which such discharges may have imbued, and finally, as regards certain contagia, the rooms in which the cases have been treated; and in order to secure these objects, it is essential in all grave cases to make such nursing-arrangements and such arrangements of the sick-room (whether private or in hospital) that no retention or dissemination of infectious matters will escape notice. It is likewise essential that all who attend on the sick should be careful not to carry contagion to other persons; as they may but too easily do, particularly in scarlatina and in certain traumatic and puerperal infections, if they omit to take special precautions against the danger. See articles QUARANTINE; DISINFECTION; and PUBLIC HEALTH; and those on the special diseases. See also Postscript, 3.

The SOCIAL CONDITIONS through which, in our own country at the present time, the more fatal infectious diseases are enabled to acquire *epidemic diffusion* are chiefly such as the following:—that persons first sick in families and districts, instead of being isolated from the healthy, and treated with special regard to their powers of spreading infection, are often left to take their chance in all such respects; so that, especially in poor neighbourhoods, where houses are often in several holdings, and where always there is much intermingling of population, a first case, if not at once removed to a special establishment, will almost of necessity give occasion to many other cases to follow;—that persons with infectious disease, especially in cases of slight or incipient attack, and of incomplete recovery, mingle freely with others in work-places and amusement-places of common resort, and, if children, especially in day-schools; and that such persons travel freely with other persons from place to place in public conveyances;—that often, on occasions when boarding-schools have infectious disease getting the ascendant in them, the schools are broken up for the time, and scholars,

incubating or perhaps beginning to show infection, are sent away to their respective, perhaps distant, homes;—that keepers of lodging-houses often receive lodgers into rooms and beds which have recently been occupied by persons with infectious disease and have not been disinfected;—that persons in various branches of business relating to dress (male and female) and to furniture, if they happen to have infectious disease, such as scarlatina or smallpox, on their premises, probably often spread infection to their customers by previous carelessness as to the articles which they send home to them; and that laundries further illustrate this sort of danger by carelessness in regard to infected things which they receive to wash;—that purveyors of certain sorts of food, if they happen to have infectious disease on their premises, by carelessness spread infection to their customers;—that streams and wells with sewage and other filth escaping into them are most dangerous means of infection, especially as regards enteric fever and cholera;—and that great purveyors of public water-supplies, so far as they use insufficient precautions to ensure the freedom of their water from such risks of infectious pollution, represent in this respect an enormous public danger;—that ill-conditioned sewers and house-drains, and cesspools receiving infectious matters, greatly contribute to disseminate contagia, often into houses in the same system of drainage, and often by leakage into wells. Of the dangers here enumerated, there is perhaps none against which the law of England does not purport in some degree to provide. At present, however, they all are, to an immense extent, left in uncontrolled operation; partly because the law is inadequate, and partly because local administrators of the law often give little care to the matter; but chiefly because that strong influence of national opinion which controls both law and administration cannot really be effective until the time when right knowledge of the subject shall be generally distributed among the people, and when the masses whom epidemics affect shall appreciate their own great interest in preventing them.

Whenever that time shall come, probably the public good will be seen to require, with regard to every serious infectious disease which is apt to become epidemic, that the PRINCIPLES which ought to be accepted in a really practical sense, and to be embodied in effective LAW, are somewhat as follows:—(1) that each case of disease is a public danger, against which the public, as represented by its local sanitary authorities, is entitled to be warned by proper information; (2) that every man who in his own person, or in that of anyone under his charge, is the subject of such disease, or is in control of circumstances relating to it, is, in common duty towards his neighbours, bound to take every care which

he can against the spreading of the infection; that so far as he would not of his own accord do this duty, his neighbours ought to have ample and ready means of compelling him; and that he should be responsible for giving to the local sanitary authority proper notification of his case, in order that the authority may, as far as needful, satisfy itself as to the sufficiency of his precautions; (3) that so far as he may from ignorance not understand the scope of his precautionary duties, or may from poverty or other circumstances be unable to fulfil them, the common interest is to give him liberally out of the common stock such guidance and such effectual help as may be wanting; (4) that so far as he is voluntarily in default of his duty, he should not only be punishable by penalty as for an act of nuisance, but should be liable to pay pecuniary damages for whatever harm he occasions to others; (5) that all who are in attendance on any case of infectious disease should be similarly bound to use every proper care and precaution not to carry the infection to any other person; (6) that the various commercial undertakings which in certain contingencies may be specially instrumental in the spreading of infection—water-companies, dairies, laundries, boarding-schools and day-schools, lodging-houses, inns, &c., should respectively be subject to special rule and visitation in regard of the special dangers which they may occasion; and that the persons in authority in them should be held to strict account for whatever injury may be caused through neglect of rule; (7) finally, that every local sanitary authority should always have at command, for the use of its district, such hospital accommodation for the sick, such means for their conveyance, such mortuary, such disinfection-establishment, and generally such planned arrangements and skilled service, as may, in case of need, suffice for all probable requirements of the district. *See* Postscript, 4.

Persons who are imperfectly acquainted with the scientific and social facts relating to the present subject-matter, or who have never seriously considered them, may think it would be over-sanguine to expect any general recognition of principles so peremptory as the above may at first appear to them; but, if so thinking, they would perhaps have under-estimated the rapidity with which knowledge is now increasing as to the common interests and mutual duties of mankind in respect of dangerous infectious disease. In the year 1865, when the so-called cattle-plague or steppe-murrain was imported afresh, as a long-forgotten disease, into this country, and was found to affect very large pecuniary interests, primarily of the chief landowners of the United Kingdom, and secondarily of other classes, an immensely valuable stimulus was given to the education of the country, and especially of its Legislature, in regard to

the preventibility of the infectious diseases. And the remarkable zeal and ability which from that time onward have been shown, in providing adequate laws and admirable administrative arrangements against the diffusion of steppe-murrain and other infectious diseases of Farm-Stock, are not likely to be found permanently absent in relation to the interests of Human Life, when once the true bearings of the subject shall have got to be popularly understood. JOHN SIMON.

POSTSCRIPT.—In revising, for the reprint of the Dictionary of Medicine, the above article, written in 1878, the writer has been able to leave the original text almost entirely without change, but has to add the following few remarks referring to steps of later progress.

1. First, with regard to the exact science of Contagion, knowledge of microphyte-life as the power of the metabolic contagia has during the past twelve years advanced considerably both in extent and in minute accuracy, and is rapidly tending to consolidate itself into general law. Work of especial value in that line has been done by Dr. Klein in respect of scarlatina and diphtheria, and also of the foot-and-mouth disease of farm-stock.

2. And with regard to the question of cases in which perhaps the microphytes of given diseases, before infecting the human body, may have multiplied in soils or waters of appropriate quality, an extremely interesting line of research has been opened by Dr. Ballard in his study of the ætiological relations of summer diarrhœa.

3. With regard to the proper action of Local Authorities against the spreading of dangerous contagions in their districts, it has to be noticed that, in 1889, an important step towards supplying the first requisite for such action was represented by the passing of an Act for the compulsory local Notification of cases of Infectious Disease (52 & 53 Vict., cap. 72).

4. Within the last few years, by the admirable studies of Mr. Power and Dr. Klein, it has been made almost certain that scarlatina and diphtheria are diseases common to man with at least some of the animals which are most intimately in his service: both of them appearing to be capable of affecting bovine animals, and to be communicable by means of cows' milk, while diphtheria appears also to be a disease which spreads among cats: and, with this extremely important addition to knowledge which previously existed, the consequence is now strongly suggesting itself that systems of law and administration intended to guard human society against dangerous infections of disease, must extend to the provision of adequate means for observing and controlling the infectious diseases of domestic and farm-yard animals, and for securing that the public health shall not be jeopardised through the negligent or wilful distribution of infected milk. J. S.

CONTINUED FEVERS.—CHARACTERS.—Under the name of Continued Fevers is included a group of diseases which have the following characters in common:—

1. They are attended with *pyrexia*, or a febrile condition sustained for a more or less definite period of considerable duration, without intermission or very decided remission, and not due to any local inflammation. That is, the fever is *essential*, and not merely *symptomatic*. The distinguishing feature of pyrexia is unnatural elevation of the temperature of the body; but there are other symptoms scarcely less constant—increased frequency of the pulse, thirst, loss of appetite, furred tongue, headache, chilliness, and—if the temperature is high—various manifestations of disturbance of the nervous system.

2. They are clearly due to the introduction into the body of a *poison from without*, and this poison is *reproduced in the system*, so that continued fevers are communicable directly or indirectly from the sufferer to others. This statement would not apply to simple continued fever so called; but simple continued fever, when not a mild or abortive attack of one or other of the specific fevers, has scarcely anything in common with them.

3. The continued fevers rarely affect the same individual twice. An attack is *protective against subsequent attacks* of the same fever. This is much less manifest in relapsing than in typhus and enteric fever.

4. The continued fevers have a more or less *definite duration*. A certain time intervenes between the exposure to the poison and the onset of the disease, which is called the period of incubation; and the disease is divisible into the stages of invasion, dominance, and decline.

5. In two out of three continued fevers there is a characteristic *cutaneous eruption*.

ENUMERATION.—The continued fevers are typhus, enteric, and relapsing fever. Common continued fever, or febricula, often associated with them for the sake of convenience, resembles them only as consisting in pyrexia not traceable to any known local inflammation. It does not conform to the characteristics enumerated, and cannot be brought within any definition which applies to the true fevers.

DIAGNOSIS.—The continued fevers have to be distinguished from the intermittent and remittent fevers on the one hand, and from the eruptive fevers and some other diseases on the other.

1. From *intermittent* and *remittent* fevers they are distinguished clinically by the comparatively sustained high temperature; but were this all, the continuous character sometimes assumed by intermittents and the remittent type occasionally seen in enteric fever—especially in children—would bring them close together. The essential distinction is that indicated under the second head, and is

mainly ætiological. Both kinds of fever are due to a poison received from without; but while in continued fevers the source of the poison is for the most part a previous case of fever of the same kind, and the poison is generated anew in the subject of the disease, remittents and intermittents are of malarious origin, and the poison is never reproduced in the system, and therefore never communicated by the sufferer.

The formation of the specific contagium of continued fevers within the system during the disease is of course the cause of their spread by contagion. The mode of this spread is different for the different fevers. Typhus and relapsing fever are directly contagious in an eminent degree; the poison is contained in the emanations from the skin or lungs, and is capable of entering the blood of healthy persons by being breathed or swallowed; it may also be carried by fomites. Enteric fever, if directly contagious at all, is very slightly so; the contagium is apparently not given off in the breath or perspiration, but chiefly or exclusively from the bowels, and the disease is spread mainly by the contamination of drinking-water, or, more rarely, by sewer gases or by the emanations from typhoid excreta, especially after long residence in sewers.

2. The distinctions between the continued and the *eruptive fevers* remain to be pointed out. They are of a very slight character. All the characters given of the continued fevers, including the occurrence of a cutaneous eruption, are common to them and the eruptive fevers. The differences are as follows:—

(a) The liability to the eruptive fevers is almost universal in the absence of protection by a previous attack, and is little affected by the state of health of the individual, while the liability to continued fever is very variable in different persons, and even races, and is greatly influenced by external conditions. There is no parallel in the eruptive fevers to the predisposition to typhus and relapsing fever generated by overcrowding and famine.

(b) The protective influence of a previous attack is more marked in the eruptive fevers, though not to such a degree as would constitute an important distinction. Instances of small-pox after a previous attack, or after vaccination, and second attacks of measles and scarlet fever, are not very uncommon.

(c) While in the eruptive fevers the specific poison is considered to be invariably derived from a previous case, this cannot be said with the same confidence with regard to the continued fevers. It is true that, in by far the largest proportion of attacks of typhus, enteric, and relapsing fevers, the source of the poison can be traced, and that as the experience and trained skill brought to bear on the search increase, the fewer are the examples in which it fails; but it cannot yet be said

definitely that these fevers are not generated anew under certain conditions. The constancy with which typhus and relapsing fever follow in the track of overcrowding and starvation is suggestive of spontaneous origin; but in this country typhus is never so completely extinct that foci of infection are wanting, and epidemics of relapsing fever may be imported. Enteric fever, again, appears from time to time under circumstances which appear to exclude the possibility of the poison having been derived from a previous case, though in most instances of epidemic prevalence of the disease, there is conclusive evidence of specific, and not merely general, contamination of the air or water. It is not, however, necessary to enter upon this controversy here, or to do more than allude to the question whether or not their contagia are of the nature of organic germs. *See* CONTAGION; and ZYME.

The fevers will be fully described under their respective names.

WILLIAM H. BROADEENT.

**CONTRACTION, Muscular** (*contraho*, I draw together).—A term applied to the action or to the shortening of a muscle from any cause, whether in health or in disease. *See* SPASM.

**CONTRA-INDICATION.**—Any circumstance which forbids the employment of therapeutic measures otherwise indicated.

**CONTRE-COUP** (Fr.), Counter-stroke. An injury of a part opposite to but distant from that to which force is applied, as by a fall or direct blow. Contre-coup is chiefly observed in injuries of the skull.

**CONTUSION** (*contundo*, I bruise).—A bruise or injury of the soft parts without breach of surface.

**CONVALESCENCE** (*con*, with; and *valesco*, I grow well).—The *period of convalescence* signifies that period during which a patient is progressing towards recovery, and is returning to a state of health after having suffered from an illness. When the health has been completely restored, convalescence is said to be established, and the patient is regarded as convalescent. The word is used most commonly in association with fevers, inflammatory diseases, and other acute affections. Convalescence may be ushered in by a crisis, and become speedily established; or it may be very slow and protracted in its progress, which is also often interrupted by relapses, complications, or sequelæ. Patients frequently require careful watching and judicious treatment while becoming convalescent, as they are apt to retard or even prevent their recovery, and to lay the foundation for permanent disease, by neglect of due precautions, especially as regards their diet. Much

injury is not uncommonly inflicted by the injudicious administration of medicines, and the employment of other means which are supposed to hasten convalescence; but, on the other hand, it can undoubtedly often be promoted by suitable measures.

FREDERICK T. ROBERTS.

### CONVOLUTIONS OF THE BRAIN and CORTEX CEREBRI, Lesions of.

The pathology of the cortex cerebri is still comparatively in its infancy. The older records and observations, made while the idea was still prevalent that the convulsions of the brain had no definite dispositions and relations, and that the various parts of the hemispheres were functionally equivalent, are not sufficiently exact to be made the basis of trustworthy clinical and physiological conclusions. Recent anatomical investigation into the topography and homologies of the cerebral convolutions, and the experimental researches of Hitzig, the writer, and others in reference to the results of electrical irritation of the brain, have directed greater attention to accurate topographical descriptions of the lesions of the cortex in connexion with observed clinical symptoms. Up to a comparatively recent date physicians and physiologists generally held by the views of Flourens, based on experimental investigation of the brains of the lower classes of animals. According to Flourens the hemispheres were concerned purely with intelligence—a faculty one and indivisible; and each part of the hemisphere possessed the functions of the whole, so that, if part were destroyed, functional compensation might be effected by the parts which remained. These views seemed satisfactorily to explain the cases, not uncommon, in which, notwithstanding the existence of extensive lesions in the hemispheres, no symptoms were observed during life. The frequent association of aphasia with a limited lesion of the cortex cerebri, vaguely indicated by Bouillaud and Dax, and definitely fixed by Broca at the posterior extremity of the third left frontal convolution, was a step towards localisation of function in the brain, which, however, met with much opposition and counter-facts. The clinical and pathological observations of Hughlings Jackson in reference to the causation of limited and unilateral epileptiform convulsions were an important contribution to the physiology and pathology of the cortex. These convulsions he attributed to irritative or discharging lesions of the grey matter in the neighbourhood of the corpus striatum in the opposite hemisphere.

Physiological experiment has demonstrated the correctness of the views advanced by Hughlings Jackson, and shown that, not only can movements be excited by electrical irritation of certain regions of the cortex, but also that definite combinations of muscular move-

ments uniformly result from stimulation of certain specialised areas within this region.

Physiological experiment is, as to precision in its results, considerably in advance of clinical observation, and, from the nature of the two methods, this is what might be expected.

The investigation of diseases of the brain is surrounded by special difficulties. Though, as shown by physiological experiment, the brain is capable of being mapped out into different regions possessing different functions, yet the brain acts as a whole, and it is not always easy to analyse the facts of disease, and to distinguish with certainty between the effects directly dependent on the locality of the brain, and those due to the indirect influence exerted on the functions of neighbouring regions and on the brain as a whole.

That the brain is diseased in insanity, functionally or organically, is a fact now universally admitted; but it is also true that the lesions which cause objective symptoms in the domain of motion and sensation need not cause mental derangement, and also that lesions which cause mental derangement need not manifest themselves in any discoverable disorders of sensation or motion. In fact, for purposes of ideation we have practically two brains; for, though motion and sensation will be paralysed on the opposite side by destruction of one hemisphere, yet intelligence and thought are possible through the hemisphere which remains.

Various forms of lesion have been found in the brains of the insane, including morbid conditions as to vascularity, degeneration of the blood-vessels, and degeneration of the nerve-cells, neuroglia, and membranes; but no constant relation has as yet been established between any one form of degeneration and any one form of mental alienation, or between the latter and any localised lesion. Nor has it been clearly established whether the forms of degeneration found in the brains of the chronically insane are the result or the cause of the mental disorders. An exception, however, is to be made in favour of general paralysis of the insane, where there seems to be a definite connexion between the anatomical lesion and the symptoms manifested. In this disease we find as a constant, if not the only factor, a form of chronic encephalitis, affecting chiefly the cortical regions which physiological experiment has shown to be the motor zone of the hemispheres. This lesion is associated with progressive motor paralysis, varied with intercurrent epileptiform and apoplectiform seizures, and with mental symptoms characterised generally by exalted ideas and delusions as to wealth, power, and grandeur. The motor symptoms are readily accounted for by the locality and character of the cerebral lesion, but the relation between this and the mental symptoms is a

subject which psychological analysis has yet to elucidate.

The objective symptoms of cortical lesions depend on their locality, and on whether they exercise an irritative or destructive influence on the parts they invade. From the localisation point of view alone the intimate nature of the morbid process is unimportant, except

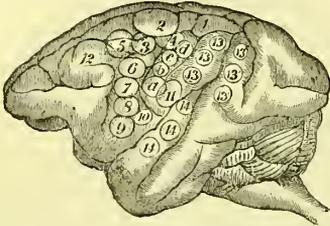

FIG. 30.—Side view of the Left Hemisphere of the Monkey. The areas have the same signification as in the next figure.

in so far as its irritative or destructive character is concerned. Lesions, such as tumours, which from their very nature exercise important indirect effects on the encephalon as a whole, apart from their effects on the regions which they directly invade, can rarely be exactly localised, owing to the difficulty of separating the direct and indirect symptoms from each other and referring each to its exact cause. Also no rigid conclusions as regards localisation can be drawn from morbid affections of the hemispheres which extend over a large area, such as the various forms of meningitis and meningo-encephalitis. In all these cases the nature of the affection must be diagnosed from its own general and special characters; its position and extent in the brain being arrived at approximately from a consideration of the effects of accurately circumscribed lesions, as determined by careful clinical and pathological observation and physiological experiment.

The brain may be considered as divided into a *motor* and a *sensory* zone.

**Motor Zone.**—The motor zone includes the convolutions bounding the fissure of Rolando, viz. the ascending frontal (pre-central), the ascending parietal (post-central), and postero-parietal lobule, the base of the three frontal convolutions, and the internal or mesial aspect of the same convolutions, or marginal gyrus. In this zone are differentiated centres for the movements of the trunk, limbs, head, and eyes, and those of the mouth, tongue, larynx, and correlated muscles. The centres of the lower limb are situated at the upper extremity of the central convolutions and in the paracentral lobule or posterior part of the marginal convolution (numerals 1 and 2, figs. 30 and 31). The centres for the foot and toes are more especially posterior to the upper end of the fissure of Rolando; those of the thigh and leg anterior to the upper extremity of the

same fissure. The centre for the arm is situated below that of the leg, and partly in front of it, and occupies the middle third, or rather two-fourths of the central convolutions (3, 4, 5, 6, 7, *a, b, c, d*, figs. 30 and 31).

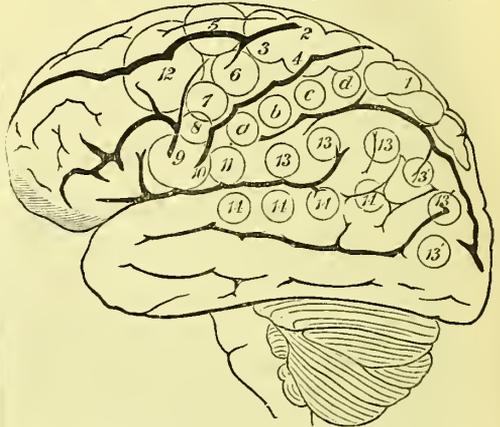

FIG. 31.—Side view of the Left Hemisphere in Man, with the areas of the cerebral convolutions. The effects of stimulation of each area, as ascertained by experiments on the brain of the monkey, are subjoined.

- 1, 2 (at the upper extremity of the fissure of Rolando). Movements of the foot and leg.
- 3, 4. Complex movements of the opposite leg and arm, and of the trunk, as in swimming.
- a, b, c, d*. Ascending parietal convolution. Individual and combined movements of the fingers and wrist of the opposite hand.
5. Posterior extremity of the superior frontal convolution. Extension forward of the opposite arm and hand.
6. Upper part of ascending frontal convolution. Supination and flexion of the opposite forearm.
7. Median portion of ascending frontal convolution. Retraction and elevation of the opposite angle of the mouth.
8. Lower part of the ascending frontal convolution. Elevation of *ala nasi* and upper lip, with depression of lower lip.
- 9 and 10. Inferior extremity of ascending frontal convolution (Broca's convolution). Movements of the mouth, tongue and larynx. Action bilateral.
11. Between the inferior extremities of the ascending frontal and the ascending parietal convolutions. Retraction of the opposite angle of the mouth; and the head turned slightly to one side.
12. Posterior portions of superior and middle frontal convolutions. Eyes opened widely; pupils dilated; head and eyes turned towards opposite side.
- 13 and 13'. Supra-marginal lobule, angular gyrus, and occipital lobe. Eyes moved towards the opposite side, with an upward (13) or a downward (13') deviation. The pupils generally contracted. (Centre of vision.)
14. Infra-marginal (superior temporo-sphenoidal) convolution. Pricking of opposite ear; head and eyes turned to opposite side; pupils largely dilated. (Centre of hearing.)

In this area may be differentiated centres for the upper arm (protraction), (5, figs. 30 and 31), and retraction (4, figs. 30 and 31); movements of the forearm, viz. flexion, supination, &c. (6, figs. 30 and 31); and those of the wrist, fingers, and thumb (*a, b, c, d*, 30 and 31).

The proximal movements of the upper extremity are represented most in the upper part of this area; the distal movements, that is those of the finger and thumb, most at the lower part. Below the arm area, and occupying the lower third of the central convolutions, is the centre for the movements of the face, mouth, and tongue and larynx, &c. (7, 8, 9, 10, 11). The upper facial movements are centralised more particularly in front of 7, 8 (figs. 30 and 31), and those of the platysma behind the fissure of Rolando (11, figs. 30 and 31). The movements of the mouth, tongue, and larynx are represented more particularly at the lower part of this area (9, 10, figs. 30 and 31). The centres for the adduction of the vocal cords are situated more particularly at the lower portion of the ascending frontal convolution, immediately posterior to the precentral sulcus. The centres for the lateral movements of the head and eyes are situated at the base of the frontal convolutions (figs. 30 and 31). The areas or centres for the head and eyes, arm and leg, extend over the margin of the hemisphere into the mesial aspect or marginal convolution. In this convolution, posterior to the centres for the head and eyes, and arm, are centralised the movements of the trunk, and, behind these, those of the leg. The prefrontal area, that is to say the region in advance of the anterior extremity of the precentral sulcus, though anatomically related to the motor tracts of the internal capsule, is a so-called non-excitable area—that is to say, it gives no outward response to electrical stimulation like the centres above described.

*Irritative lesions* of the motor zone proper, such as may be induced by syphilitic lesions, tumours, spicula of bone, depressed fractures, thickening of the membranes, &c., cause convulsions, which may remain limited to one limb, or one group of muscles, without loss of consciousness, or affect the whole of the opposite side with loss of consciousness, or become more or less bilateral with all the symptoms usually observed in so-called idiopathic epilepsies.

If the convulsive phenomena begin always in the same way, and if they frequently remain localised in one limb or one group of muscles, and especially if paralytic symptoms manifest themselves, the exact position of the lesion in the opposite hemisphere may be accurately diagnosed.

*Destructive lesions* of the motor zone cause general or limited paralysis of voluntary motion in the opposite side of the body, according as the lesion affects the whole of the motor zone, or is limited to special centres within this area. The causes of destructive lesions of the cortex may be various—hæmorrhage, laceration by wounds, &c. One of the most common causes is embolism or thrombosis of the arteries supplying the cortical motor area. These are derived from the

Sylvian artery of the middle cerebral. The cortical branches may be occluded without interfering with the circulation in the corpus striatum, which is supplied by special branches, as shown by the researches of Duret and Heubner.

When the motor zone is affected by a general destructive lesion, complete hemiplegia of the opposite side results, in all respects like that resulting from destructive lesion of the corpus striatum and anterior portion of the internal capsule. In this form of paralysis the loss of motion is most marked in those movements which are most independent; hence the arm is more paralysed than the leg or face, and the hand more paralysed than the shoulder movements of the arm. This has been accounted for by the fact, that the centres for bilateral movements are intimately associated in the lower ganglia; hence the stimulus from one hemisphere can to a certain extent call forth the action of the conjoint motor nuclei. The electrical contractility and nutrition of the muscles is not affected by paralysis of cerebral origin. The nutrition of the muscles may, however, suffer from disuse, and frequently paralyses of cortical origin are followed after a time by rigidity and contracture, with descending sclerosis of the pyramidal tracts of the crura, pons, and lateral tracts of the spinal cord. In some cases the descending degeneration invades the anterior cornua of the spinal cord, and atrophy of the paralysed muscles ensues. Occasionally from limited lesions of the cortical motor area complete hemiplegia may occur on the opposite side, for the time at least. This is to be explained by the fact that sudden establishment of a destructive lesion may cause such commotion or perturbation of the centres in general, that their functions are for the time suspended. But in such cases those centres which have been only functionally suspended again resume their functions, and the paralysis disappears except of those movements the centres of which have been permanently damaged.

Limited lesions of the motor zone cause paralysis of those movements the centres of which the lesion invades. The result is not complete hemiplegia, but a *monoplegia* or *dissociated* paralysis. Hence, from a cortical lesion we may get a paralysis of the arm, or of the arm and face, or of the leg and arm, or of the face alone, or of the lateral movements of the head and eyes. If the leg is specially paralysed, the lesion is in the upper third of the central convolution; if the arm, in the middle third of the central convolution; if the face, in the lower third of the central convolution, and we may more precisely localise the lesion in the upper or lower half of these respectively, according as the proximal or distal movements are more particularly affected. The lesion which, while circumscribed at first, causes a monoplegia, may

advance to other centres, and after a time produce general hemiplegia of the opposite side. Hemiplegia so resulting is a succession of monoplegia, and is a sure indication of cortical disease. It is to be noted that destructive lesion of the mouth-centre (Broca's region) on one side does not cause paralysis of articulation or phonation, owing to the fact that each centre has a more or less complete bilateral influence over the movements of the mouth and tongue and larynx. Destructive lesion of this centre in the left hemisphere generally gives rise to aphasia without paralysis of articulation (see APHASIA). In bilateral lesions there is both aphasia and paralysis of articulation (see Dr. Barlow's case, *Brit. Med. Journ.* 1877, vol. ii. p. 103). Limited cortical motor lesions are frequently associated with transitory rigidity of the opposite side of the body; and occasionally also with unilateral convulsions, owing to the morbid process inducing irritation of the neighbouring centres.

Unilateral destruction of the oculo-motor area causes a temporary conjugate deviation of the head and eyes to the side of lesion, a condition which is frequently seen in the early stages of hemiplegia, and it is due to the unantagonised action of the centre in the sound hemisphere. But the effects of unilateral destruction of this centre are not permanent, hence lesion of this region may appear entirely latent. Lesions of the pre-frontal region cannot with certainty be diagnosed. Not infrequently they give rise to an irritable dementia; but it is difficult to distinguish this from the general symptoms of other forms of cerebral disease, such as tumour, abscess, and the like.

Subcortical lesions of the motor zone cause symptoms not readily, if at all, distinguishable from lesions of the cortex itself. They are perhaps less frequently quite limited, owing to the close relation of the various tracts converging towards the internal capsule, though occasionally they have the character of differentiated monoplegia. Theoretically, according to the results of experiment, irritative lesions of the medullary fibres should produce only tonic, and not clonic, epileptiform spasms of the related muscular groups; but, practically, this is not a reliable test, inasmuch as these lesions are apt to cause also cortical irritation and clonic convulsions of the usual type.

In the majority of instances of paralysis from disease of the cortex sensation has been unimpaired; but, on the other hand, a number of cases have been put on record in which, with lesions of various kinds (including tumours) implicating the motor zone, there has been paralysis, not only of motion, but also of sensation in a greater or less degree. But, whereas paralysis of motion is invariably caused by truly destructive lesions of the motor area, anaesthesia is only of occasional occurrence in connexion with apparently

similar lesions. There is no relation between the extent, degree, or duration of the motor paralysis and the impairment of sensation; for there may be the most complete paralysis of motion with perfect sensibility in all its forms, cutaneous as well as muscular; and the motor paralysis may remain when the anaesthesia, if any, has entirely disappeared.

The centres of common and tactile sensibility have been shown by the writer's experiments, and those of Horsley and Schäfer, to be situated in the falciform or limbic lobe, and many of the recorded cases of anaesthesia in connexion with lesions affecting the motor zone can be shown to have directly implicated either this lobe or the sensory tracts of the internal capsule, and we may legitimately assume, even if we cannot demonstrate, a similar direct or indirect implication of these regions in the case of others. The slight degree of anaesthesia affecting the fingers more particularly which has been most frequently noted in connexion with cortical motor paralysis, is, in the writer's opinion, to be regarded as the beginning or the remnant of a general hemianæsthesia, due to direct or indirect implication of the sensory tracts.

**Sensory Zone.**—Experiments on monkeys and other animals, by the complementary methods of excitation and destruction, have shown that in the regions behind and below the motor zone there are differentiated centres for the senses of sight, hearing, common and tactile sensibility, smell, and taste.

The experiments of the writer indicate that the *visual centre* is situated in the angular gyrus and occipital lobe, or occipito-angular region; though those of Munk and Schäfer would limit this centre to the occipital lobe. Unilateral lesion of the angular gyrus, or occipital lobe, may remain latent; but if it is such as to cause extensive destruction of the medullary fibres of this region, homonymous hemianopia towards the opposite side is the result. This is particularly frequent in connexion with lesions invading the mesial aspect (cuneus) of the occipital lobe. Destructive lesions of the angular gyrus of the left hemisphere commonly cause word-blindness, and allied defects in visual ideation. Hemianopia may be caused also by lesion of the optic tract, or of the corpora geniculata. Uncomplicated hemianopia from cerebral lesion is comparatively rare. Usually it is associated with some degree of hemianæsthesia, owing to implication of the adjacent sensory tracts, or, it may be, with a greater or less degree of hemiplegia. In cerebral hemianopia, a pencil of light thrown on the anaesthetic side causes contraction of the pupils; whereas, if the lesion is in the optic tract no reaction occurs (Wilbrand's test). Irritative lesions of the angular gyrus not infrequently give rise to subjective ocular spectra, or visual hallucinations.

The *auditory centre* is situated mainly,

if not exclusively, in the superior temporal gyrus. Owing to the bilateral relations of each centre, unilateral lesion may cause no appreciable symptoms. If, however, the lesion is in the superior temporal gyrus of the left hemisphere, word-deafness is usually met with. This does not occur in connexion with lesion of any other part of the temporal lobe, provided that the superior temporal gyrus is intact. Deafness from cerebral disease is very rare. In order that this should occur, it is necessary that the superior temporal gyrus should be destroyed on both sides. There are only two cases on record of such a bilateral lesion; one reported by Shaw (*Archives of Medicine*, February, 1882), and another by Wernicke and Friedländer (*Fortsch. d. Med.*, March, 1883). In both cases total deafness was observed. In monkeys, however, complete destruction of this region on both sides does not entirely abolish sensitiveness to sonorous vibrations (*Croonian Lectures on Cerebral Localisation*, Ferrier, 1890). There are several cases on record of irritative lesions of this region causing subjective auditory sensations, or epilepsy ushered in by an auditory aura (*ibid.*).

The centre of tactile and common sensibility is situated in the falciform or limbic lobe, as above mentioned (gyrus fornicatus and gyrus hippocampi). This conclusion is founded almost entirely on the results of experiments on monkeys. Pathological evidence in favour of the localisation of the tactile centre in this region is as yet scanty.

Experiments on monkeys indicate that the centres of smell and taste are situated in close relation to each other at the lower extremity of the temporal lobe, or region of the hippocampal lobule (see *Croonian Lectures, sup. cit.*).

The anatomical relations of the olfactory tract, as well as the results of electrical stimulation, indicate that the olfactory centre is chiefly in relation with the nostril on the same side, and cases have been reported in which smell has been affected on the same side as the cerebral lesion. But the facts of cerebral hemianæsthesia, functional and organic, indicate that some at least of the olfactory tracts pass into the opposite hemisphere by way of the internal capsule. It was supposed by Meynert that the olfactory tracts decussate in the anterior commissure, but this is opposed by the anatomical and experimental investigations of von Gudden and Ganser. There are several cases on record of subjective olfactory sensation in connexion with tumours and other irritative lesions implicating the region of the uncinate gyrus in man (Jackson and Beever, *Brain*, October, 1889). The exact position of the centres of taste has not been determined either by experimental research or by clinical observation, but the evidence is in favour of their being situated in close relation to those of smell.

TREATMENT.—The principles of localisation above indicated, combined with those of antiseptic surgery, have in recent years been in several instances successfully applied to the treatment of certain forms of cerebral disease otherwise hopeless ('Cerebral Localisation in its Practical Relations,' Ferrier, *Brain*, 1889; and *ibid.*, Mills). These include traumatic cysts and extravasations, the position of which has been determined by the symptoms, as well as cases of tumour and abscess, the last more particularly in connexion with disease of the middle ear. Excisions of irritable portions of the cortex have also been undertaken for the cure of focal epilepsy; in some instances with benefit, though in others without material improvement.

Up to the month of December, 1889, eighteen cases of cerebral tumour had been operated upon. Of these, seven were successfully removed. Of the remaining eleven cases (including three cases of tumour of the cerebellum, and five of unremovable tumours, two of them operated on *in extremis*) nine have died from various causes, including septic inflammation, cerebral œdema, or shock. This gives a mortality of fifty per cent. Contrasted with the latest statistics of trephining for all causes, or of the mortality from the major operations in surgery, we have reason to regard the surgical treatment of cerebral tumour as having achieved an encouraging measure of success, and probably greater successes may be attained in future when the conditions of successful operation and after-treatment have become better known. In the absence of definite indications as to the character of the tumour, and as to whether it is situated on, in, or beneath the cortex, trephining is, in the writer's opinion, justifiable as a diagnostic measure; for if the tumour should, after all, not be removable, the risks of the operation itself are less than the evil of allowing a case to perish which the autopsy might prove to be one which could have been dealt with successfully.

D. FERRIER.

CONVULSIONS.—SYNON.: Eclampsia; Fr. *Convulsions*; Ger. *Krampf*.

DEFINITION.—This term is commonly given to more or less general, purposeless muscular contractions, occurring simultaneously and successively for a variable time—constituting a 'fit' of this or that kind. It is also, however, applied at times to certain more localised purposeless contractions, though these would be more appropriately (and are in the majority of cases) termed *spasms*. The latter, like convulsions, are of two kinds, *tonic* and *clonic*.

CLASSIFICATIONS.—Convulsions have been variously classified by different authors according to the different points of view from which they have been regarded. From the point of view of their causation, it was the

custom of older writers to recognise both a clinical and a physiological division into classes. From the former standpoint there was the division into (1) primary or essential; (2) sympathetic; and (3) symptomatic: whilst from the physiological point of view convulsions were divided into (1) centric; and (2) excentric. These classifications are altogether arbitrary and superficial, and will not stand the test of a critical examination—though the first of them is to a certain extent useful. Again, looking to the distribution of the convulsions, or to the parts involved, the classification that has been adopted by various writers may be summarised as follows:—(1) *external convulsions*—*a*, general; *b*, unilateral; *c*, partial; (2) *internal convulsions*.

These various terms need little explanation, though before referring to a more recent and more strictly scientific classification something requires to be said in regard to them.

Convulsions are termed *primary* or *essential* when they occur either without assignable cause, from mental or moral perturbations, or as a result of some local irritation. They are called *sympathetic* when the convulsions declare themselves as a prelude to, or in the course of, any of the specific fevers, as a consequence of acute pulmonary or renal affections, or in association with disordered states or structural diseases of any of the organs of the body other than those of the nervous system; while the name *symptomatic* has been applied to the convulsions which occur as a result of injury or structural disease of the nervous system itself. The unilateral convulsions which affect one half of the body only, as well as other more partial convulsions, are almost entirely confined to this latter group, though general convulsions of the symptomatic type are perhaps just as frequently met with. The so-called *internal convulsions* constitute an ill-defined group, the members of which are scarcely worthy of the name of convulsions at all. They are rather tonic or clonic spasms of particular parts. The best-known member of this group is laryngismus stridulus; but another example is a spasmodic and frequently recurring hiccup. Some authors would also include angina pectoris.

Convulsions, either tonic or clonic, or both, enter into or form the semeiological basis of six principal diseases having separate places in our nosology. These are *eclampsia*, *epilepsy*, *tetanus*, *laryngismus stridulus*, *hydrophobia*, and *chorea*. All but the first of these conditions will be considered in their respective places, so that eclampsia alone remains. But eclampsia and convulsions are convertible terms, meaning almost absolutely the same thing. The former term, indeed, is useless except for the mere purpose of literary precision. In epilepsy and in eclampsia we have equally to do with convulsions, which are now admitted

by almost all modern writers to be, so far as the form of the attack is concerned, indistinguishable from one another. The former name, however, is given to convulsions which have a known tendency to recur at variable intervals; whilst the latter has been commonly applied to convulsions which are either solitary or, if not exactly so, which occur as a closely successive cluster or group, more or less distinctly sympathetic with some general or local bodily condition. Seeing that there is, in a very large number of cases, almost nothing in the nature of the attack itself to enable a medical man, called to a patient in convulsions for the first time, to say whether he has to do with an attack which will be repeated or not, it is easy to understand that eclampsia is a word more frequently to be seen in books than to be heard at the bedside. In books we may read of *eclampsia neonatorum*, the eclampsia of parturient women, and *uræmic eclampsia*; though the more common clinical equivalents are *infantile convulsions*, *puerperal convulsions*, and *uræmic convulsions*. The distinction between epilepsy and eclampsia is, therefore, one which is to a very great extent purely artificial, from the point of view of the convulsions themselves.

Convulsions have a frequent though less constant relationship also with many other affections, such as general paralysis of the insane, tubercular meningitis, chronic hydrocephalus, hemiplegia, and hysteria.

The more recent classification of convulsions, previously referred to, is that of Dr. Hughlings Jackson (*Brit. Med. Journ.*, vol. i. 1890). This is an attempt in the right direction—an attempt, that is, to identify the intimate cause of the phenomena, and to range convulsions into different classes according to the different portions of the brain which are the seats of the initial morbid processes in this or that form of the disease. He recognises three kinds of convulsion; each kind including several varieties; and these varieties again comprehending 'fits' of many different degrees of severity. The *first* kind or class corresponds with epilepsy proper, and these attacks are dependent, as he thinks, upon discharges of nerve-elements occurring in some portion of the cortex of the prefrontal lobe; the *second* kind or class comprises what are known as epileptiform attacks (epileptic hemiplegia or Jacksonian epilepsy), due to discharges commencing in this or that portion of the cortex of the so-called 'motor area' (Rolandic region) of the cortex; whilst the *third* kind or class comprises what he terms 'pontobulbar fits,' being due, as he thinks, to initial discharges of nerve-elements occurring in some part of the pons, the bulb, or (much more rarely) the spinal cord.

The aim of this classification is essentially scientific, but even its main divisions are

based to a very large extent not so much upon well-ascertained facts as upon hypothesis and speculation. This is especially the case, as Dr. Hughlings Jackson admits, in regard to the convulsions belonging to the first and third classes; though the pathology of the second class—to a very large extent as the result of his labours—stands upon a much firmer basis of actual knowledge. Some kinds of eclampsia would fall into the first class, whilst many others would belong rather to the third class. It is difficult to say into which category well-developed hystero-epileptic attacks should be placed. It must not be lost sight of, moreover, that the conceptions which have inspired this classification are eminently hypothetical and speculative, however ably and consistently they may have been worked out; so that our notions as to the mode of production of fits, and as to the natural groups into which they are to be ranged, should still be regarded as being in a very rudimentary stage.

**ÆTIOLOGY.**—The causes of convulsions are oftentimes more than usually complex, constituting a web of conditions partly made up (*a*) of predisposing, partly (*b*) of exciting, and partly (*c*) of proximate elements. It is often the fashion to pick out some one of the most prominent or easily recognisable of these factors, and speak of it as 'the cause' of the attack. It must never be forgotten, however, that this so-called cause, in any given case, may be able to act as such only when in conjunction with certain other more obscure, though perhaps not less potent, co-operating conditions.

The question of the causation of convulsions resolves itself into a strictly clinical and a strictly physiological department. It is one thing for the medical man to ascertain what are the particular individual states, conditions of life, and occurrences, physical or moral, which have contributed to induce an attack of convulsions. It is quite a different problem when he endeavours to unravel, by physiologic-anatomical data, the actual mode of production of the convulsions. For the present this is a point of view which concerns us less than the more strictly clinical side of the inquiry.

**Predisposing causes.**—One of the most important of these is the existence of an unduly excitable nervous system—one in which there is an exaltation of the tendency to produce reflex movements. This is a state of things which is often more marked in women than in men, and is also notably prominent in young children of both sexes. It is, moreover, much exaggerated in some children of nervous habit, who, besides being unduly emotional or excitable, are very prone to start or tremble at the least noise, and are subject to muscular twitchings in various parts of the body. With increasing age, and more especially in the male sex, we find the

sensorial and emotional nerve-centres becoming less excitable.

In persons possessing a nervous system of this type there is a lack of proper balance or equilibrium between the functional activities of some of its parts; and there seems to be an undue tendency to errors of nutrition whereby the matter of its nerve-cells becomes from time to time highly unstable and prone to undergo 'discharges' of a morbid character.

The predisposing groundwork being of this nature, how is it caused or to be accounted for? (1) It may be inherited from parents, or from grandparents, who may themselves have possessed a nervous system of this type, and may have been subject to fits or other well-marked disease of the nervous system. But though not inherited in the strict sense of the term, it may (2) be connate: the patient may always (*i.e.* from birth) have possessed a nervous system of this type, as an accompaniment of the mere low vitality which is often seen in children born from parents who are weak or aged and debilitated. (3) At other times the nervous system may have acquired such predisposing characters some time during the life of the individual (especially during childhood or adolescence) owing to the action of various sets of conditions, such as—(*a*) the cachexia which occasionally follows measles, pertussis, &c.; (*b*) insufficient or improper food; (*c*) chronic diarrhoea; (*d*) hæmorrhages or exhausting discharges.

If we turn now to the various *exciting causes*, we find these powerfully influenced by the periods of age, which we may conveniently, though artificially, mark off from one another.

**Infancy** (from birth to end of 2nd year).—In certain cases convulsive attacks are congenital; and here perhaps the most frequent exciting cause is a meningeal effusion of blood which irritates the surface of the brain—the extravasation having been occasioned during parturition. These congenital attacks are most frequently associated either with more or less marked hemiplegia, or with a subsequent partial or distinct condition of amentia or idiocy. Such unfortunate infants may continue quite unable to stand or even sit up; they remain unable to speak, and, as in a case seen by the writer, the child may be quite blind. Meningeal or superficial hæmorrhages may also occur in young infants, under the strain produced by violent fits of coughing; and in some of these cases such effusion may be followed by convulsions. Fits in infancy may also follow falls or blows upon the head.

In infancy, again, convulsions may usher in or supervene in almost any acute disease, this being especially the case in the exanthemata; in pneumonia or bronchitis; and also in tubercular meningitis.

But, still more frequently, convulsions in infancy are excited by mere peripheral irrita-

tions, as during the process of teething, from an overloaded stomach, or from indigestible food. Diarrhœa and worms also take their place as more or less frequent excitants of convulsive paroxysms in infants, though worms only begin to appear towards the end of this period. But though irritations in the field of distribution of the fifth and pneumogastric nerves are especially potent in exciting convulsions, irritations of other parts of the body may also lead to similar results, whether they are occasioned by the injudicious disposition of pins, by tight strings wounding or irritating the skin of the body, or by any other means. The more distinctly that predisposing conditions exist, the more frequently will any or all of these exciting causes give rise to an attack of convulsions.

Lastly, an infant which has taken the breast of a woman who has shortly before been much perturbed by violent anger, grief, or any other strong emotion, may thereafter, if predisposed, be seized with convulsions—probably owing to the milk of the nurse having been so altered in quality as to have led to gastric trouble and irritation in the infant.

*Childhood* (from the 2nd to the 13th year). Most of those exciting causes which are influential during the previous period continue to be occasionally operative in this—especially during the first half of it. Meningeal hæmorrhages are now rarer, though they may still occur during violent paroxysms of coughing, and also from falls or blows upon the head. The latter causes of hæmorrhage may, however, act in producing fits in other ways, *e.g.* by concussion, shock, &c., and they now come to be more frequently operative. The exanthemata are still apt to be preceded or associated with convulsive attacks; and irritations, especially from teething or irritants (undigested food or worms) in the intestinal canal, are also occasionally prone to be followed by such a sequence.

During this period another cause comes into operation with great frequency, and this is fright. The first fit either follows the fright more or less immediately, or it may not take place for days, or perhaps for weeks. During the interval, however, the health and mental condition of the child is generally obviously disturbed. Proper treatment at this stage may prevent the occurrence of fits. Scrofulous or other tumours in the brain sometimes help to determine convulsions in children.

*Adolescence* (from the 13th to the 20th year).—Fright or other sudden emotions, falls upon or blows about the head, still appear as frequent excitors of convulsive attacks which recur (epilepsy) at this period of life, though meningeal hæmorrhages, acute diseases, and peripheral irritations are much less frequently operative than at earlier periods, since the special irritability of the nervous system characteristic of childhood decidedly abates during these years.

Other and new causes, however, come into play at this epoch. The establishment of puberty is a kind of crisis during which, independently of all other causes, convulsions or fits may be initiated in those whose nervous systems are at all predisposed towards such an occurrence. This is more especially so in the case of the female, partly because of the existence of a rather more frequent predisposition in persons of this sex, and partly because of extra excitations in association with the establishment of the catamenia. Ovarian or uterine irritation, or irregularity of the functions of these organs at this period, may occasion fits which may take an hysterical type. Masturbation may also be added as an occasional provocative of epilepsy at this critical period of life, though the writer is inclined to think too much stress is often laid upon this as a cause. This mode of causation occurs more frequently with the male sex.

Excessive study and mental application, as well as worry or anxiety, must also undoubtedly be enumerated among the causes of epilepsy at this period of life.

Neither must we forget the possible existence of aneurysms of the cerebral arteries, or of morbid growths in connexion with some portion of the brain or its meninges. This latter cause also figures in earlier periods of life—more especially in those children who are of a scrofulous type. And in some of such cases the new-growth may lead to the supervention of chronic hydrocephalus, and thus render the occurrence of convulsions even still more likely.

*Early adult age* (20-40 years).—Fits originate much less frequently during this period of life than in adolescence or childhood. They are, however, apt to supervene, more especially when the general health is lowered, under the influence of various exciting causes. Grief and mental worry (particularly when combined with long-continued bad sleep), and the labours or cares of business, are then apt to induce them.

Blows or falls upon the head may still be followed by attacks of this kind, though perhaps with less frequency than in the earlier periods of life.

Syphilitic indurations or growths from the meninges may now occur; and other attacks (often of one-sided convulsion) may be determined by various pathological changes or accidents taking place in regions of the brain where more severe lesions would give rise to hemiplegia. The primary change in these cases may be minute hæmorrhages into the brain-substance, or minute and slight softening produced by blocking of small vessels (embolism or thrombosis). With lesions of this kind hemiplegia and convulsions are often more or less associated. Occasionally the cause may be a non-syphilitic tumour, occupying the side or base of the brain.

Puerperal convulsions in the female, and uræmic convulsions in both sexes, are most frequently met with during this period. During pregnancy the excitability of the nervous system is often greatly increased, and in the production of puerperal convulsions some amount of uræmia also intervenes not infrequently. Intemperate habits, carried to excess, frequently produce fits, and so also may venereal excesses.

*After middle age* (40 years and onwards). The excitability of the nervous system diminishes, so that epileptic attacks commence with much less frequency at this period. At the climacteric this excitability is temporarily increased, and fits again become more frequent, under slight exciting causes.

Although fits are only very rarely liable to be induced by the sequelæ of hæmorrhages or of occlusions of cerebral vessels, yet these events now grow more common as age advances, and are therefore to an almost corresponding extent more liable to figure as causes of convulsive attacks. An attack of hæmorrhage or of softening may be ushered in by epileptiform convulsions (especially when the lesion occurs in certain parts of the brain), and in some cases such attacks may thereafter recur at irregular intervals. Exposure to great heat, or sunstroke, may also at this period, or earlier, act as the exciting cause of convulsions.

Mental overwork, worry, fright, and such-like influences, are much less likely to operate in persons over 40 than in earlier life; and the same is to be said of blows or injuries of the head, short of the most severe, causing actual lesions of the brain. But the malnutrition and degeneration induced by intemperate habits may predispose to symptoms of this kind; and so also may blood-poisoning from renal disease, which is often present.

Various organic diseases of the brain, whether principally characterised by degenerations with a process of more or less general atrophy, or with localised overgrowth of connective tissue, are also not infrequently productive of convulsions, either in persons of middle or of advanced age. A well-marked instance of the former of these associations is to be met with in general paralysis of the insane. Cysticerci on the surface of the brain have also been the cause of most obstinately recurring convulsions.

Lastly, it should always be borne in mind that convulsions are sometimes the result of the action of poisons of various kinds upon persons of any age. Occasionally such poisoning may be brought about by articles of diet, such as mussels or fish in certain states, or poisonous mushrooms; whilst at other times it results from some of the well-known narcotico-irritant poisons, taken either inadvertently or purposely.

**ANATOMICAL CHARACTERS.**—These may be

said, so far as our present knowledge goes, to be absent. It is true that general or partial congestion of the brain may frequently be encountered in those who die during an attack of convulsions. But this congestion is to be regarded as a result rather than as a cause of the fit. The convulsions are due to mere molecular changes in the brain, inappreciable to, or at all events unappreciated as yet by, the most skilled microscopists. When fits occur in association with actual organic growths or other lesions of the cerebral cortex or elsewhere, some of the nerve-cells contiguous to such lesions may have their nutrition so altered as to form occasional starting-points for nervous discharges, which descend so as to upset the equilibrium of certain unstable or highly charged motor centres (ponto-cerebellar) in such ways as to determine the convulsive phenomena. But a similar disturbance of nervous equilibrium with discharge of motor energy, immediately productive of convulsive phenomena, may result, in another case, from abnormal visceral impressions (induced, it may be, by indigestible matters in the intestine, or by an acute disease of the lungs), or from some surface-irritation. In accordance with this point of view, such organic growths or other lesions as may be found in the brains of epileptic patients need receive no further mention here. Those who may be inclined to think otherwise, should bear in mind the fact that convulsive attacks are easily produced in animals from whom the cerebral hemispheres have been removed. It should always be borne in mind, however, that there is one region in particular of the cerebral cortex, viz. the so-called Rolandic area (comprising the convolutions which bound the fissure of Rolando), the irritation of which by new-growths or other organic lesions is specially prone to give rise to unilateral convulsions, whose characteristics are in many respects extremely well-defined ('Jacksonian epilepsy').

**SYMPTOMS.**—The varied nature of the causes makes it impossible to say anything of moderate compass concerning the premonitory signs or symptoms which may precede an outbreak of convulsions. These must necessarily vary immensely in different cases. Some of the characters of the predisposing state have been already alluded to. The onset is, however, often abrupt, and without any distinct premonitory symptoms.

With regard to the actual characters of the attack, it will be sufficient to say here that they also vary extremely in different cases; and as, notwithstanding this great variability, it is impossible in any individual case to tell, from the nature of a first convulsive fit, whether it will form a more or less isolated attack, or whether it will constitute one of a subsequently recurring series, the reader may, for this part of the subject, be referred

to the description of the different forms of the attack given under EPILEPSY. All that is there said concerning the actual phenomena and mechanism of the attacks, holds good for occasional convulsions as well as for those which are habitual. In each well-marked attack we have to do with (1) a more or less distinct stage of tonic spasm, followed (2) by one of clonic spasms, and (3) succeeded by a state of stupor. One or other of such stages is, however, not infrequently more or less abortive. Convulsive attacks may, at times, so rapidly follow one another as to be merged into one long series or *status convulsivus*, differing in no respect from the analogous *status epilepticus*.

COMPLICATIONS AND SEQUELÆ.—The complications of convulsions are most various, seeing that in different cases we may have to do with irritated gums, repletion, diarrhœa, worms, or an acute specific disease; whilst in other cases the causal complicating conditions may be general debility and sleeplessness, mental anxiety, puberty, or the climacteric period. Again, in other cases, either pneumonia, renal disease, pregnancy, ovaritis, or some organic brain-disease may be the accompanying condition.

The nature of the sequelæ will depend principally upon the frequency of the attacks, and the duration of the period during which the patient has been subject to the recurrence of them, so that for this part of the subject the reader may refer to the article EPILEPSY.

DIAGNOSIS.—There is very little difficulty in regard to the diagnosis of convulsions. The differential characters of laryngismus stridulus are given elsewhere, and the absence of any real distinction between a fit of eclampsia and a fit of epilepsy has already been insisted upon. Neither of these affections can be easily confounded with certain forms of chorea, which occasionally present themselves in adults, with movements not unlike those of ordinary convulsions. The more continuous nature of the movements, and the fact that consciousness is not impaired, suffice to distinguish all forms of chorea. The spasms of tetanus and hydrophobia are also easily distinguishable from an ordinary attack of convulsions.

The characteristics of hysterical convulsions are pointed out in the article HYSTERIA.

The real difficulties from the point of view of diagnosis have reference to the cause of the attack. To arrive at a decision in regard to this is often very difficult, and occasionally impossible—at all events when a patient first comes under observation. At other times, however, the indications are so plain that there can be little or no difficulty. It is a question which should always be considered with the utmost care, since on the correctness of our conclusions in regard to this point the efficacy of the particular line of treatment which we adopt must necessarily depend.

Nothing is more to be deprecated than hasty jumping at conclusions, from mere routine and superficial considerations. The condition of the patient must be carefully examined, and the nurse, attendants, or relatives must be closely questioned in order that we may learn as much as possible as to the previous state of health of the patient, and more especially as to the time and events which immediately preceded the first outbreak of an attack of convulsions. Examination and inquiries combined may convince us that the convulsions are (1) of the primary or idiopathic variety, immediately occasioned perhaps by fright, anxiety, overwork, overmuch or indigestible food, &c.; or we may come to the conclusion that the convulsions are (2) of the sympathetic order, dependent upon pregnancy, renal disease, the onset of an acute specific fever or of pneumonia, or due to the existence of whooping-cough, scarlet fever, &c. Or, in the absence of reasons for placing them in either of these categories, we may be forced to conclude that they are (3) symptomatic of some organic brain-disease, the nature of which must then be determined as nearly as possible, judging from the age of the patient, the mode of onset of the attacks, his present state and associated conditions.

In any case we may have to inquire more closely as to the hereditary tendencies, or acquired predisposing causes, which sometimes reduce the nervous system to such a degree of excitability, or disturbed equilibrium of certain parts, as to lead to an attack of convulsions without the aid of any obvious exciting cause. In infants or very young children such a condition of the nervous system may display itself by great restlessness and startings at night, by the child's sleeping with half-open eyes, by drawing in of the thumbs across the palms, by twitchings of the limbs, of the angles of the mouth, or of the facial muscles generally. In older children and in young adults the signs which most easily mark a similar below-par condition of the nervous system are twitching of the muscles about the angle of the mouth, and of the tongue (the former being specially well seen when the latter organ is tremulously protruded for inspection), associated with debility, anorexia, partial insomnia, and general nervousness. In nervous girls fits are induced by very slight causes about the time when the catamenia become first established. The indications for treatment must in fact vary immensely in any five or six consecutive cases of convulsions to which the practitioner may be summoned.

PROGNOSIS.—The possibilities under this head are at least six in number in regard to any case of convulsions:—(1) The patient may recover after having a single fit or a batch of them within a few hours or days, and may never have another attack. (2) The

patient may recover, and though he or she may not have fits habitually thereafter, they may recur at prolonged intervals, whenever predisposing circumstances chance to be strong or are supplemented by an exciting cause of unusual potency. Thus convulsions during teething may cease, and may not recur till the constitution has been lowered by some illness years after, or when the nervous system has been rendered more irritable, as at the time when the catamenia are about to commence, especially if then some slight fright should also come into operation as an exciting cause. (3) The patient may recover, though he subsequently continues to have fits either at irregular or regular intervals; he becomes, in short, a confirmed epileptic. (4) The convulsions may come to be followed by temporary delirium or a more or less marked maniacal condition, recurring after all or some seizures. (5) The patient may recover from the convulsive attack and may or may not have another fit, though he may remain hemiplegic. (6) The patient may die during the attack or almost immediately afterwards—(a) from the effects of it, or (b) by reason of some organic lesion by which the fit itself has been determined.

Recoveries are fortunately the rule, but death, especially in infants, is by no means uncommon. We possess no accurate data to enable us to assign the numerical proportion of these terminations to one another or to the other above-mentioned sequences.

**TREATMENT.**—During the convulsion itself, whether we have to do with an infant or an adult, we must see that all clothes are thoroughly loose about the neck and chest, and the patient should be placed in the supine position with the head slightly raised. Beyond seeing that the patient does not knock or injure himself, owing to the violence of his movements, these should not be much restrained; although efforts should always be made to prevent the tongue being bitten, by slipping the most suitable thing at hand between the molar teeth on one side, when the age of the patient or the character of the fit renders it likely that this event might otherwise occur. Beyond such simple measures as these, the less we do during the actual continuance of the fit the better it will probably be for the patient. We know of no rational or successful means of cutting short an ordinary attack of convulsions, and in the face of such an attack we should be cautious how we interfere lest evil may be done.

Where we have to do with a succession of attacks quickly following one another, and which have already lasted some time, the injection into the rectum of chloral hydrate, with or without bromide of potassium, in suitable doses may be beneficial; or the careful administration of chloroform may be tried, as it is found very serviceable in many cases when a *status convulsivus* occurs in

children or in adults—though it would not be desirable to have recourse to it in infants. Under similar circumstances, for the latter the warm bath may be substituted, and sometimes seems to do good. Antipyrin and antifebrin have also occasionally been given with benefit in cases where fits are succeeding one another rapidly, and such drugs are especially indicated in those cases where the temperature in the rectum rises rapidly to 103° F., or upwards.

On the cessation of the convulsion or convulsions, or during the intervals, the treatment to be adopted to prevent their recurrence must necessarily vary immensely according to the age of the patient, and according to the predisposing and exciting causes which appear to have been operative in inducing the attack.

An overloaded stomach will call for the speedy administration of an emetic; or where indigestible food has already passed into the intestine, an enema or brisk purgative should be given. Diarrhœa must be checked, or anthelmintics administered when worms are suspected. Gums may be lanced if they seem really to need it. In many of these cases an acquired or hereditary predisposition will have to be combated by the careful regulation of the diet, so that nutritious and easily digested food is to be given in place of their opposites, and at the same time the most suitable nervine tonics and antispasmodics.

For general usefulness in such cases no remedies can compare with the bromides of potassium, sodium, and ammonium. The former salt seems to be the most potent of the three; though if the bromide of sodium will check the fits, it is often more desirable to give it than the potassium salt. On the other hand, where the circulation is weak, or mental depression is apt to be induced, it is often best to administer bromide of ammonium. Sometimes the best results may be obtained by giving two of these salts in combination; at other times by administering moderate doses of chloral hydrate in combination with one or other of them. As part of the specific influence which these drugs exercise over nerve-tissue, they fortunately establish a tendency to quieter and sounder sleep, of which such patients often stand much in need. Ten-grain doses three times a day should be given at the commencement to youths or adults, and afterwards slightly increased if necessary. Or a larger dose may be given once a day, either in the morning or at night, or night and morning, according to the indications in each case.

Very large doses of these drugs are rarely beneficial, and may do harm (*see* BROMISM). Their action often seems to be favoured and harmful symptoms warded off by combining with the bromides suitable doses of liquor arsenicalis and tincture of digitalis or of convallaria. Quinine or belladonna are other

remedies which may also often be given simultaneously with great advantage. For young children or infants, the dose of the bromide must, of course, vary with their age.

Valerianate of zinc and oxide of zinc are mostly remedies of altogether less power, though these and other drugs may be tried where bromides appear to fail. Occasionally, too, good results may follow from the administration of borax in doses of fifteen or twenty grains three times a day, freely diluted and combined with liquor arsenicalis, where bromides only seem to aggravate the patient's condition, or, at least, to be powerless for good.

General treatment of this kind is applicable to a large proportion of cases also in which in debilitated or 'nervous' patients fits have been brought on by fright, worry, or anxiety, or by no assignable cause. Wherever the fits have recurred frequently, and a sort of habit has thus been established, such treatment has to be continued over long periods (one to three years or more), with suitable modifications, in order to stamp out the tendency to recurrence and thus effect a cure. In all such cases fatigue of mind and body is always to be avoided; a quiet and regular life, free from excitement, must be led; and in those instances in which over-attention to business or over-study has been in part operative in bringing on the fits, absolute rest must form an essential part of the treatment. In girls or young women in whom fits occur at the time of the establishment of the catamenia, or where they recur in association with an irregular menstrual function, the general health often requires our most careful attention, in addition to such measures as are above indicated.

The convulsions that belong to the class known as *sympathetic* have to be carefully considered in relation to the malady of which they are the forerunners or associates. When convulsions precede an attack of scarlet fever or of small-pox they usually subside of themselves as the disease develops. They are, however, of much more significance when occurring during the course or towards the close of one of these maladies, or during an attack of whooping-cough or of croup. Our indications for treatment must then be derived in the main from the general state of the patient, and this is also eminently the case where we have to do with uræmic convulsions.

The treatment of *symptomatic* convulsions, dependent upon actual organic brain-disease, must also necessarily be subordinated to that appropriate for the affection itself upon which such symptoms depend. No drug will be found more generally useful, however, than bromide of potassium in ten- to fifteen-grain doses for an adult (administered three times a day), in checking or diminishing the repetition of convulsions in these cases. Often here also the action of the bromide seems to be favoured by combining it with liquor

arsenicalis and with moderate doses of digitalis, the latter being indicated especially in those cases in which there is great general nervousness in association with a disordered cardiac rhythm. Where sounder sleep is necessary, chloral hydrate, alone or in combination with bromide of potassium, should be given at bedtime. Sulphonal often has the desired effect. Tinctures of sumbul or of henbane are at times useful adjuvants.

Where we have to do with tumours of the brain, and especially with syphilitic growths in the meninges, much better results are to be hoped for from large and increasing doses of iodide of potassium (that is, x to xxx grains or more, three times a day), either alone or in combination with small doses of bichloride of mercury. With such drugs we should combine the administration of nutritious food, and attention to the improvement of the general health in every way that may be possible. Occasionally, both in these cases and in non-specific cortical growths and thickenings of the dura mater, the operation of trephining has been had recourse to with great benefit to the patient. In some instances a cortical growth, or a portion of cicatricial tissue or of thickened dura mater, has been excised, with the effect not only of curing previous pain and tenderness, but also of curing or greatly diminishing the frequency of epileptiform attacks to which such patients have been subject. The cases for which this treatment is suitable constitute, however, only a comparatively small percentage; and much judgment and knowledge are needed for the selection of those in which such surgical treatment is likely to prove beneficial. See BRAIN, Diseases of; EPILEPSY; and SPINAL CORD, Diseases of.

H. CHARLTON BASTIAN.

**CO-ORDINATION.**—This term is used in reference to muscular movements principally. Certain parts of the nervous system have more especially to do with the calling into activity, and therefore with combining, the contractions of different muscles, both simultaneously and in succession, in the precise order in which they occur in the several motor acts of which they are capable. The nervous arrangements upon which these actions depend have come into being, both in the race and in the individual, by processes of organic growth and development *pari passu* with the possibility of executing these several movements. It would be wrong to expect, therefore, that an isolated organ should exist solely for co-ordinating muscular movements. The execution of the most habitual of these must depend, to a large extent, upon the activity of the ordinary motor (and related sensory) tracts of the spinal cord and brain. The extent or precise mode in which the cerebellum intervenes in certain higher forms of co-ordination is still involved in much

obscurity. That it has some share in such functions may be regarded as certain, though it probably intervenes far less than some would have us believe, who regard the cerebellum as the organ for the co-ordination of muscular movements.

Many nervous affections exist in which the co-ordination of muscular movements is more or less impaired. One of the most familiar of these is locomotor ataxy, a disease dependent upon a morbid process in the posterior columns of the cord. Sclerosis of the antero-lateral columns of the cord also not infrequently disturbs the execution of muscular movements, especially those of the upper extremities. Chorea gives rise to very similar uncertainties in the execution of muscular acts. Spasms of all kinds, in short, tend to interfere with the harmony of the muscular movements in the course of which they intervene. Stammering is an affection of this kind, implicating some of the muscles of articulation; and certain disturbed cardiac actions characterised by disordered rhythm can only be regarded as belonging to the same category.

The above-mentioned are common instances of impaired co-ordination of muscular movements dependent upon structural or functional changes in parts of the nervous system other than the cerebellum. Certain diseases of this organ, however, are known to give rise to a distinct form of inco-ordination. It is characterised by a reeling, unsteady gait in walking, with legs straggling, and mostly wide apart, to which the term 'titubation' is commonly applied. Other kinds of inco-ordination may hereafter be proved to depend upon diseases of the cerebellum. Its morbid conditions are still very imperfectly recognised, and this is especially true in regard to its merely functional perturbations.

Certain inco-ordinations in speech and writing are common. Instances are to be found in that use of wrong words or misapplication of terms which we meet with in aphasic and amnesic persons; also in the substitution of wrong words in the act of writing, or of wrong letters in the writing of words, when such substitution is mechanical and unintentional—and when it is wholly distinct, therefore, from mere inability to spell. These defects are inco-ordinations of a complex kind, dependent upon the perverted action of higher cerebral centres, in the same way that incoherent speech generally is dependent upon incoherent thought. There is reason to believe, indeed, that the same kind of ultimate defective nervous action which leads to inco-ordinations of movements when certain motor regions of the nervous system are affected, may, on the other hand, give rise to perverted perceptions (*illusions*) or to perverted thought (*incoherence*) when the disturbed nervous action occurs in other and in higher parts of the central nervous system.

**COPHOSIS** (κωφός, deaf).—Deafness. See HEARING, Disorders of.

**COPPER, Poisoning by.**—SYNON.: Fr. *Empoisonnement par le Cuivre*; Ger. *Kupfervergiftung*.—*Metallic copper* may be regarded as innocuous when swallowed, and the recent researches of Hirt show that those who are engaged in the metallurgy and manufacture of copper utensils are not specially liable to any diseases which can be attributed to copper as such. It is, indeed, stated that workers in copper enjoy an immunity from cholera, a conclusion which is based on very insufficient premisses. It is contradicted by the occurrence of cholera among coppersmiths in Breslau in 1866, and by certain other cases of a like nature reported by Hirt. That the disease is seldom found among workers in copper is true, but that the copper has anything to do with this result is not proved.

Though pure copper may be regarded as innocuous, it is otherwise with *alloys of copper*, more particularly those with zinc and tin, known under the names of brass and bronze respectively, and with compounds of copper with lead or arsenic. In these the injurious agent would appear to be the alloy, and not the copper itself. An affection of a febrile character, and known as 'brass-founder's ague,' occasionally occurs on fusing days, and it is attributable to the zinc fumes which are generated by the melting process.

The *salts of copper*, on the other hand, are capable of causing injurious and fatal results. The more important salts, from a medico-legal point of view, are the sulphate, blue vitriol, or bluestone; the acetates (basic and neutral) constituting artificial verdigris; and the carbonate or natural verdigris. The manufacture of verdigris is carried on to a large extent in the South of France. Plates of copper are acted on by the skins of grapes, which are allowed to undergo the acetous fermentation. Those engaged in this industry on the whole enjoy good health, and it is only rarely that symptoms can be directly traced to the work; and then only when through sheer carelessness and uncleanness quantities of the salt have been ingested. It is even said that dogs eat the refuse grape-skins without appearing to suffer from poisonous symptoms. On the other hand, symptoms of poisoning of a family have recently been recorded where they had eaten haricot beans, grown, as is the custom, between the vines, which latter had been watered with a solution of sulphate of copper (Raynaud, *Bull. Gén. de Thérap.*, 1888).

1. **Acute poisoning by copper.**—SYMPTOMS.—The salts of copper, when taken in sufficient quantity, cause symptoms of acute poisoning, frequently terminating fatally.

Twelve to fifteen grains of the acetate have been sufficient to kill a dog within an hour. The fatal dose in man is not quite determined; but doses above the usual emetic dose of the sulphate (ten to fifteen grains) have caused serious symptoms, and death has resulted within four hours after swallowing some pieces of the sulphate. Starr (*Med. Record*, May 1882) records a case of death in four days from one ounce of the sulphate. Half an ounce would probably cause a fatal result. The symptoms are essentially those of irritant poisoning, namely, styptic or coppery taste, constriction of the fauces, epigastric pain, violent vomiting and purging, followed by collapse and death, usually with tetanic or convulsive symptoms. That which characterises copper-poisoning more especially, as compared with other irritants, is the frequent occurrence of jaundice. Hæmoglobinuria with albuminuria has also been observed (Starr's case). In dogs copper usually causes death with symptoms of paralysis of the hinder extremities, proceeding like a form of ascending paralysis, in addition to the usual irritant symptoms. It is said also to have a paralysing action on the heart. Such effects have only followed, at least constantly, introduction into the veins; when taken by the stomach most of it seems to be stopped by the liver, or in the case of some of the salts (*i.e.* acetate) may be reduced by the sugar of the food (Roger, *Revue de Médecine*, 1887, No. 11).

2. **Chronic poisoning by copper.**—It is generally stated that the long-continued introduction of copper into the system in small doses gives rise to a form of chronic poisoning known under the name of 'copper colic.'

**SYMPTOMS.**—The symptoms are essentially those of gastro-intestinal irritation, with nausea or sickness and diarrhœa. They have none of the characters of colic in the sense in which the term is usually employed. The hair and the cutaneous secretions of workers in copper and brass are sometimes found of a green colour, and a line is sometimes found at the margin of the gums and teeth, variously described by authors—Corrigau calling it purple, while Clapton calls it green.

Though symptoms of gastro-intestinal irritation, as above described, have been found among workers in copper, the question is whether they are in reality due to the copper, or merely symptoms of a not uncommon affection showing themselves among copper-workers. That copper does gain access into the system, and may be detected in the urine during life, and found in the bones after death, without the individual showing any manifest symptoms during life, seems pretty well established. But though we may regard it as certain that symptoms of copper-poisoning are more rarely found than those of lead-

poisoning among those who have to deal with these metals, yet it would be a very unwarrantable conclusion, and contrary to all that we know of the action of poisons, to assert that a substance which is undoubtedly poisonous can be taken freely into the system with impunity. This is a point of considerable interest in reference to the accidental or wilful adulteration of articles of food with copper salts. Many cases are on record of severe symptoms resulting from the use of copper utensils in cooking, or more frequently from the storage of water or articles of food in copper vessels, especially if the food contains oil—which, on turning rancid, dissolves the copper—or vegetable acids, or even large quantities of ordinary salt.

Copper salts are also employed intentionally to impart a green, fresh colour to pickles and preserved vegetables, such as peas. It is asserted that the quantity of copper necessary to produce this effect is infinitesimal, and that no poisonous effects can be proved to have resulted even from long-continued employment of these vegetables as articles of food. This is strongly maintained by M. Galippe, who has tried them on himself and family. Assuming the impossibility of proving the injurious effects of copper-tinted vegetables, the question comes to be principally a social and economic one, as to the propriety or legality of adulteration of food at all, and especially with a substance undoubtedly poisonous. Copper is said by Odling and Dupré to be a natural constituent of the human body. They have found it in the blood, tissues, viscera, and in many animal products, such as cheese, eggs, and also in many vegetables. It takes the place of iron in the blood colouring-matter of some invertebrates (cray-fish), and is found as a constituent of the colouring-matter of the feathers of the turaco (plantain-eater).

**DIAGNOSIS.**—The greenish or bluish colour of the vomited matters, which turn bright blue on the addition of ammonia, renders the diagnosis comparatively easy.

**TREATMENT.**—In *acute* cases the stomach should be evacuated by encouraging vomiting, or by the stomach-pump. Albumen in some form, as milk or white-of-egg, should be given, in order to precipitate the copper. Iron filings may be given for a similar purpose.

In *chronic* poisoning the cause should be discovered and removed, or the individual removed from the cause. D. FERRIER.

**CORN.**—**SYNON.**: *Clavus*; Fr. *Clou*; *Cor*; Ger. *Leichdorn*; *die Hühnerauge*.

**DEFINITION.**—A corn is a thickening of the epidermis, caused by undue pressure and friction, as by boots, shoes, or implements of occupation. It is usually situated on a prominence, such as that of a joint, where the skin is subjected to double pressure

and is therefore unable to yield, or between the toes. Corns are most common on the feet.

**DESCRIPTION.**—A corn usually begins as a general and uniform thickening of the epidermis, which is termed a *callosity* (*tyloma*, *tylosis*, *Schwiele*). Callosities may occur on any part of the integument. Thus they may occupy the prominence of a joint, or spread over the heel or the metatarsal cushion of the foot from pressure in walking, or occupy the metacarpal prominences of the hand, as in boatmen.

The callosity is composed of laminated epidermis; is thickest in the centre, becoming thin towards the circumference; and is more or less hard and condensed, smooth and hornlike in appearance, and yellowish in colour. When the irritation which gives rise to a callosity is prolonged, effusion is apt to take place beneath it, and it is raised like a blister, the effused fluid being sometimes serous and sometimes sero-purulent. Whenever this happens, the subsequent separation of the horny layer results in spontaneous cure.

When the pressure giving rise to a callosity, instead of being diffused, is concentrated on a central point, the epidermis corresponding with that point increases in thickness, by its under surface, and forms a conical prominence; further pressure increases the length and breadth of the cone, and in this way a corn is established. Continued irritation enlarges the corn by hyperplasia of epidermic cells, and its pressure produces absorption of the derma, sometimes extending to the bone itself. Not infrequently effusions of serum or blood take place beneath the conical prominence; and, in rare instances, a bursa is found between the corium and the joint.

At a late stage of its growth the corn has the appearance of a central core—technically, *the eye of the corn*—surrounded by a collar of smooth epidermis in the state of callosity. The core is a lamellated ovoid mass, corresponding in external figure with the cup by which it is produced; and consisting in substance of vertical cup-shaped lamellæ closely packed one within the other. In an old corn the shape of the entire core is conical, the point resting on the sensitive skin, and the signification of the term *clou* or nail thus applied by the French is made manifest. The substance of the corn resembles horn both in colour and density, but between the toes, where moisture is generally present, it remains white and soft, like soddened cuticle, and is thence named *soft corn*. Effusion at its base is more common in the soft than in the hard corn.

**TREATMENT.**—The treatment of a corn is to remove its causes, namely, pressure and friction; but when this is impracticable, to equalise pressure, by which the corn will

revert to the state of callosity. The second indication is best effected by some simple unirritating application, such as the soap- or lead-plaster spread on washleather. As a preliminary to this application, as much of the hard epidermis as possible should be removed by soaking and scraping, and the core turned out with a blunt-pointed instrument. The soft corn may be removed as the hard one, or by snipping with scissors. When there is inflammation about the corn, it should be treated by water-dressing. Chronic corns are much benefited by an application composed of Salicylic Acid, 30 parts; Extract of Indian Hemp, 5 parts; Flexile Colloidion, 240 parts.

ERASMUS WILSON.

**CORNEITIS.**—Inflammation of the cornea. See EYE AND ITS APPENDAGES, Diseases of.

**CORNUAL** (*cornu*, a horn).—Relating to the cornua or horns of grey matter of the spinal cord, e.g. *cornual myelitis*. See SPINAL CORD, Diseases of.

**CORONARY ARTERIES, Diseases of.**—SYNON.: Fr. *Maladies des Artères Coronaires*; Ger. *Krankheiten der Kranzarterien*.—The diseases of the coronary arteries may be classified as follows: (a) atheroma and calcification; (b) aneurysm; (c) occlusion of the orifice; (d) thrombosis and embolism; and (e) syphilitic disease.

a. **Atheroma; Calcification.**—Atheroma and calcification of the coronary arteries are frequent, but by no means constant, sequelæ of similar changes in the root of the aorta. The disease may be general, affecting both vessels equally or unequally; or it may be limited to one of them, or even to a primary branch of either; and may lead to fatty degeneration or fibroid change of the corresponding substance of the heart. The experiments of Mr. Erichsen and M. Schiff have proved that the nutrition of the heart in health depends upon a free coronary circulation, and pathology has confirmed this conclusion. Sir Richard Quain found the coronary arteries diseased or obstructed in 13 out of 33 cases of fatty degeneration of the heart, and in one of these cases, the trunks of both vessels being healthy, a calcified coronary branch led to the only portion of the heart exhibiting fatty change. Of 55 cases of fatty degeneration of the heart collated from the *Transactions of the Pathological Society of London*, 21 exhibited atheromatous or calcific change of the coronary arteries. In 10 of these death occurred by rupture of the left ventricle, in 1 by rupture of the right ventricle, and in 2 by rupture of the septum ventriculorum, the coronary branch leading to the seat of rupture having been, in every instance, in a more advanced state of disease than the other portions of

the vessel. From the foregoing statistics it would appear, that whilst fatty degeneration of the heart may exist independently of disease of the coronary arteries, the latter condition may be regarded as an *immediate* cause of fatty change in the heart, in the proportion of about 38 per cent. of all cases. Hüfer points out (Virchow's *Archiv*, vol. lxxxix. 1882) that fibroid disease of the heart is frequently associated with sclerotic changes in the coronary arteries, the fibroid patches corresponding to the site of the changes in the arteries. Fibroid disease may also be produced as a result of embolism of the coronary vessels.

**SYMPTOMS AND SIGNS.**—There are none which are peculiar to this disease; those which exist being due to the consecutive changes in the substance of the heart. The doctrine formerly held, that calcification of the coronary arteries was the cause of angina pectoris, is no longer tenable, though fatal cases of angina are more frequently associated with disease of these vessels than with any other lesion. It is probable, however, that the affection of the coronary arteries produces angina only by disturbance of the functions of the cardiac nerves and ganglia. See ANGINA PECTORIS.

**b. Aneurysm.**—Aneurysm of the coronary arteries is of rare occurrence. It is usually preceded by atheromatous or calcific changes in the coats of the vessels, and may, therefore, be regarded as a disease of middle or advanced age. Dr. Gee has, however, published an example of coronary aneurysm in which the patient was a boy of only seven years.

**SYMPTOMS AND SIGNS.**—There is no positive indication of coronary aneurysm during life. When the termination is fatal, as it usually is, death occurs by hæmorrhage into the pericardium from rupture of the sac.

**c. Occlusion.**—Occlusion of the orifices of the coronary arteries has been met with only in connexion with calcific changes in the root of the aorta, a partially detached calcareous plate overlying the orifice of either vessel (both are rarely affected), and partially or completely shutting off the circulation. There are no *symptoms* distinct from those of the principal disease.

**d. Thrombosis and Embolism.**—*Thrombosis* of the coronary arteries is a frequent result of disease in the coats of these vessels; and owing to their small size, complete blocking and arrest of circulation through them are the ordinary consequences of this accident. *Embolism* of the coronary arteries has been observed in cases of endocarditis especially involving the mitral valve. The heart-substance, depending upon the occluded vessel for its vascular supply, quickly undergoes the atrophic changes of fatty or fibroid degeneration; or appearances like those found in infarction in other viscera

are produced. Special *symptoms* are entirely wanting.

Disease or obstruction of the coronary arteries, with the ordinary consequences—fatty degeneration of the heart, and anæmia with white softening of the brain—are conditions usually found in cases of permanently slow pulse.

**e. Syphilis.**—Syphilitic disease of the coronary arteries has been recorded in a number of instances, but its identification depended entirely upon the history and the concomitant symptoms, the deposit being histologically indistinguishable from ordinary atheroma.

THOMAS HAYDEN. C. J. NIXON.

**CORPORA AMYLACEA** (*corpus*, a body; and *amyllum*, starch).—These minute bodies, which were first described in this country by Sir Richard Quain and Dr. Hughes Bennett in the 2nd and 3rd vols. of the *Transactions of the Pathological Society of London*, were thus named by Virchow. They are generally visible only with the aid of the microscope, but sometimes are large enough to be seen with the naked eye, and now and then attain some size. Usually they are round or oval, and present a concentric, laminated arrangement, which is made more apparent by the action of acetic acid. They often have a yellowish tinge. In appearance corpora amylacea somewhat resemble starch-granules, and they are tinged brown or bluish by the action of iodine upon them. These bodies were formerly supposed to be composed of starch, and hence their name. This is not the case, however, and their actual chemical composition is not clearly known; it probably differs in different structures. Bodies resembling corpora amylacea in appearance and arrangement have been found in various parts, but they have attracted most attention in connexion with the nerve-centres, being particularly observed when these are the seat of atrophy or degeneration; they are especially seen in the choroid plexus.

FREDERICK T. ROBERTS.

**CORPORA QUADRIGEMINA**, Lesions of.—The facts of comparative anatomy and experimental physiology tend to show that the corpora quadrigemina (*corpora bigemina* or *optic lobes* of the lower vertebrates), though related to the optic tracts, do not correspond in their development to the eyes or oculo-motor apparatus, and appear to be largely concerned in those functions, such as equilibration and locomotor co-ordination, which are independent of the cerebral hemispheres.

The facts of human pathology, though not opposed to these data, cannot be made the basis of very precise conclusions as to the diagnostic indications of disease of these ganglia, as it is exceedingly rare to find disease such as local softening limited to

this region anatomically or functionally, and hæmorrhage is unknown.

The corpora quadrigemina are, however, not infrequently involved in lesions which invade neighbouring parts, such as meningitis—simple and tubercular, tumours, especially of the pineal gland and the middle lobe of the cerebellum, &c.

It is stated by experimenters on the lower animals (pigeons, &c.) that when the anterior tubercles, which are more especially connected with the optic tracts, are destroyed, vision is abolished, and that if the lesion is unilateral, the blindness occurs on the side opposite the lesion.

It is questionable whether such results occur in man, apart from indirect implication of the optic tracts (neuritis). Dr. Bastian, however, has recorded a case of total blindness, in which the cause proved to be softening limited to the anterior tubercles of the corpora quadrigemina (*Paralysis from Brain Disease*, p. 115).

It has been found experimentally in animals, and also in man, that atrophy of the opposite tubercle ensues when the eye has been destroyed. Irido-motor action is also paralysed by destruction of the corpora quadrigemina, a result which, however, is stated not to occur unless the injury is more than superficial and implicating the oculo-motor nuclei.

Disturbances of equilibration and co-ordination also result from lesion of the corpora quadrigemina. These are attributed to implication of the subjacent tracts, and, according to Lussana and Lemoigne, more particularly to lesion of the subjacent superior cerebellar peduncle. For his own part, the writer thinks that all attempts at differentiation are pure hypotheses, and from the nature of the question must remain so. But, from whatever cause, there is no doubt that the disturbances alluded to do occur.

Irritation of the corpora quadrigemina on one side causes dilatation of the pupil and a hemiopisthotonos of the opposite side, which becomes general if the irritation is prolonged or bilateral, the head being retracted and the legs extended, trismus also being very marked. According to Lussana and Lemoigne unilateral lesion of the corpora quadrigemina causes an incurvation of the trunk and gyration to the side of the lesion. This would agree with the effects of irritation, being naturally a reversal of the phenomena. Tumours implicating the corpora quadrigemina are generally associated with a reeling gait, which is an early symptom, and also frequently with symptoms of ophthalmoplegia from implication of the oculo-motor nuclei. The affection of the ocular muscles is unequal, according to the degree in which the respective nuclei may be affected by the lesion (Nothnagel). In a case reported by Dr. Duffin (*Trans. Clin. Soc. of London*, vol. ix.), which

the writer had an opportunity of investigating, of tumour of the pineal gland, which, besides passing forward into the third ventricle, pushed underneath the aqueduct of Sylvius, stretching and causing atrophy of the corpora quadrigemina, the symptoms, in addition to those of cerebral tumour—namely, violent occipital headache and double optic neuritis—were double vision followed by loss of sight, vertigo, specially marked when the eyes were open, staggering gait, and tendency to retraction of the head and rigidity of the dorsal muscles. The pupils were large and sluggish. These symptoms, to a certain extent, resemble those caused by tumour in the middle lobe of the cerebellum, and it is a question how far these latter may be due to mechanical irritation of these ganglia. But we may infer that such a combination of symptoms as the above points to lesion of the corpora quadrigemina, or of the middle lobe of the cerebellum, though we cannot be certain of the absolute limitation of the lesion.

Naturally the same secondary affection of the functions of the cerebral hemispheres occurs from tumours situated in this region, as in tumours of the middle cerebellar lobe.

Pressure on the veins of Galen leads to dropsy of the cerebral ventricles, and its consequences on the cerebral circulation and functions.

D. FERRIER.

**CORPULENCE** (*corpus*, a body).—An undue accumulation of fat in the body. See OBESITY.

**CORPUSCLE** (*corpusculum*, a little body).—In physiology and pathology this word is generally used as synonymous with cell. See CELL.

**CORPUS STRIATUM**, Lesions of. The corpus striatum of English anatomy and pathology comprises various structures which have received special names—namely, the *nucleus caudatus*, or intra-ventricular nucleus, which is exposed to view by laying open the lateral ventricle; the *nucleus lenticularis*, or extra-ventricular nucleus, consisting of three divisions, and subjacent to the convolutions of the island of Reil; together with the anterior division of the *internal capsule*, or peduncular expansion, which connects the cortex and crus cerebri.

This differentiation is necessary, as the effects of lesion of the corpus striatum will differ according to whether the grey matter alone, or the internal capsule, is involved.

Physiological experiment has not succeeded in defining the respective functions of the ganglionic masses of the corpus striatum. The experiments of Aronsohn and Sachs, Ott, Hale White, and others seem to show that lesions of these ganglia in animals cause a rise of several degrees in body temperature from increased heat-production.

The corpus striatum is especially liable to lesion from embolism or rupture of its blood-vessels. These are furnished principally by the middle cerebral artery, which in the first part of its course sends off numerous straight twigs, which sink into the anterior perforated space, and supply this ganglion and the adjacent part of the optic thalamus. Owing to their position, and direction as regards the main current, they are easily ruptured or blocked up, and owing to their being of the nature of 'end arteries,' and almost destitute of anastomoses with other cerebral arteries, embolism rapidly leads to softening of the regions which they nourish.

**SYMPTOMS.**—The symptoms of lesion of the corpus striatum may be divided into three groups or stages.

*First stage.*—This includes certain symptoms which are more or less transient, and depend chiefly on the suddenness of the lesion and functional disturbance of other parts.

To the latter belong the symptoms usually accompanying an apoplectic seizure (apoplexy), as also the loss or diminution of sensation on the opposite side of the body, which sometimes occurs in consequence of pressure on, or functional interference with, the sensory tracts of the internal capsule by effusion into the corpus striatum. The symptoms due to the suddenness of the lesion of the corpus striatum, as such, are complete paralysis of every voluntary movement on the opposite side of the body, occasionally varied by convulsive spasms of the paralysed side, and conjugate deviation of the head and eyes towards the sound side. This latter symptom is due to the centres for the head and eyes of the opposite hemisphere suddenly losing their antagonists. The temperature of the paralysed side is, as a rule, higher than that of the sound side. The total paralysis and flaccidity of the opposite side of the body, and conjugate deviation of the head and eyes, are transient symptoms, lasting from a few hours to a day or two.

*Second stage.*—This stage includes those symptoms which continue for a variable period, after those depending on the suddenness and disturbing effect of the lesion have passed off. They constitute the common type of hemiplegia or paralysis of voluntary motion on the side opposite the lesion. The face, arm, and leg, and to a certain extent the thoracic and abdominal muscles on the one side of the body, are affected. The paralysis does not affect all these parts equally. As a general rule it may be stated that those movements are most affected which are most independent of those of the opposite side, and which are most complex and delicate. Hence the movements of the hand and arm are more affected than those of the face or leg, owing to the fact that these are more commonly exercised in associated or

alternating action with those of the other side. The facial paralysis is most marked in the lower facial region. The orbicularis palpebrarum is more or less paretic, but never paralysed to the extent which occurs in Bell's or true facial paralysis, depending on lesion of the portio dura. The angle of the mouth on the paralysed side hangs lower, and the tongue deviates slightly to the paralysed side. The weakness of the facial muscles is best brought out when the patient smiles or tries to whistle. The face then becomes drawn to the sound side. While some volitional control may have been acquired over the leg, the hand and arm remain perfectly motionless.

In the process of recovery, the leg recovers before the arm, and as a rule the recovery proceeds from the proximal to the distal end of the limb, the shoulder and hip movements being regained before those of the hand or foot. The flexors regain their power before the extensors.

The sensibility of the paralysed parts is unimpaired. The superficial reflexes are diminished, the deep (tendon) reflexes increased.

The faradic contractility of the muscles is unimpaired; occasionally it is increased rather than diminished.

The muscles do not undergo atrophy except by disuse.

The temperature of the paralysed limbs, which at first is usually increased, is generally found to be lower than that of the sound side, to the extent of a degree, more or less.

Recovery may take place from all the symptoms of this stage, within a period varying from weeks to months, or the patient may pass into the third stage.

*Third stage.*—The special symptoms of this stage are the occurrence of what is termed 'late rigidity' in the paralysed limbs, a condition of evil import. This rigidity shows itself most frequently in the arm, but it is common enough in both limbs. The rigidity affects the flexors more particularly, and causes the limb to assume a position in which the flexors predominate. It is variable in degree, and at first is capable of being overcome. At first, also, it is remittent, tending to give way when the patient abstains from volitional efforts or from excitement, and seems almost gone on waking from sleep or when the patient yawns or stretches himself. Gradually it assumes a more intense form, and the limb becomes permanently fixed and rigid.

After death, this condition is found to coincide with descending sclerosis of the motor tracts of the brain and spinal cord. The degeneration proceeds from the seat of lesion downwards through the crus, pons, and pyramid of the same side, and then across to the posterior part of the lateral column of the spinal cord on the paralysed side. Frequently, also, a similar track of degeneration is found

on the inner aspect of the anterior column of the spinal cord, and occasionally also in the lateral column on the same side as the brain-lesion (Charcot, Türck, &c.)

Even during the rigid stage, there is, as a rule, no trophic degeneration of the muscles or annihilation of faradic contractility, though the muscles waste from disuse unless artificially stimulated. But in some rare instances, as Charcot has shown, the secondary degeneration invades the anterior cornua of the spinal cord, in which case amyotrophy or trophic degeneration of the muscles ensues.

There is no recovery from this condition.

*Variations and complications.*—Though general hemiplegia of the opposite side, without affection of sensation, is the type of disease of the corpus striatum, certain variations and complications have been observed, some of which still require elucidation.

When sensation is permanently affected along with voluntary motion, we have reason to regard the lesion as not confined to the corpus striatum, but as implicating also the posterior part of the internal capsule and the thalamus, an occurrence by no means rare. When the lesion affects only the grey matter of the nucleus caudatus, the hemiplegia is, as a rule, comparatively slight and transitory.

Similar affection of the nucleus lenticularis is said to produce more marked paralysis than that caused by affection of the nucleus caudatus, but also not of a permanent kind. When, however, the lesion causes rupture of the anterior two-thirds of the internal capsule, the hemiplegia is most marked and most enduring. It is this lesion only which gives rise to secondary degeneration of the motor tracts and permanent rigidity.

Cases are on record in which lesions of the corpus striatum have given rise, not to general hemiplegia of the opposite side, but to monoplegia, such as paralysis of the face or of one or other limb. But these monoplegiæ are without doubt due to limited lesions of the internal capsule, which, as the researches of Franck and Pitres and of Beevor and Horsley have demonstrated, contains the motor tracts corresponding to the differentiated centres of the cortex.

Cases are also on record of paralysis occurring on the same side of the body as the lesion. The real existence and explanation of such exceptional occurrences are still *sub judice*, and though various explanations may be suggested, it is well to wait for further instances, carefully investigated by accurate modern methods, before pronouncing definitely on the question.

D. FERRIER.

**CORRELATION.**—This term is used in medicine almost exclusively in reference to the ætiology of disease, and in this relation principally in regard to the zymotic diseases. The term 'correlation of the physical forces'

may be taken as implying that the several forces are capable of being converted into or of giving place to one another when they are permitted to act under certain conditions, and that they are all related to a common cause. It is very much the same idea that is implied by the term 'Correlation of the Zymotic Diseases,' a subject which has been discussed in a separate work by A. Wolff.

It is contended that the several contagious diseases of a general type (the exanthemata) do not, necessarily and in all cases, reproduce their like; but that occasionally, the contagious particles thrown off from the same sick person suffering from one of the diseases (*e.g.* scarlatina) may suffice to engender one or more different kinds of disease, according to the mode in which this matter operates—that is, according as it may be swallowed, taken into the system through the pulmonary surface, or through some other mucous membrane or skin-abrasion. These diseases are said to be correlated, therefore, on account of this assumed relation to a common cause—a specific contagium. According to this notion the seat of primary action and the constitutional condition of the patient are factors which largely influence the form of disease that ultimately manifests itself as a result of the contact of any given contagium. This view has at present scarcely passed beyond the stage of an ingenious speculation—though it is one which is by no means unworthy of further attention, opposed though it may be to many current doctrines as to the specific and unalterable nature of contagia.

Of late years, moreover, evidence in support of some such doctrine has been strengthening. Thus, to take one example, it has now been shown (*see* Dowdeswell's Report in *Brit. Med. Journ.*, July 19, 1884) that two very distinct forms of septicæmia exist of an extremely contagious character, which may take their origin from common putrefactive material introduced into different parts of the body. The one, known as 'Davaine's septicæmia,' may be set up by introducing two or three drops of putrid blood beneath the skin of an animal; whilst a totally different form of the disease, known as 'Pasteur's septicæmia,' may be induced by introducing a similar quantity of the same putrid blood into the peritoneal cavity of another individual of the same kind of animal. The late Professor Hueter, indeed, held, as a result of experimental observations, that the contagia of many diseases are derivable from common septic organisms and their alkaloids, by virtue of alterations taking place under particular conditions in the process of putrefaction, by which means the common organisms take on 'specific modes of activity.' Instances of such conversion, as well as of the interchangeable morphological characters of bacilli and micrococci associated with different contagious processes, are cited

by him and also by Professor Fokker of Groningen. See *Trans. Intern. Med. Cong.* 1881, vol. i. pp. 329-334.

Diseases may be said to be correlated also when they are severally related to the same cause acting with different degrees of intensity. Thus it is held by some epidemiologists that the plague is only a malignant form of typhus; that yellow fever is due to a more intense form or action of the same poison as suffices at other times to engender intermittent or remittent fever; and that summer diarrhoea, cholera, and cholera are also but different manifestations of one common though variable cause.

Similarly it is held by many surgeons that ordinary surgical fever, pyæmia, and septicæmia are correlated effects, due to the action of the same poison in different degrees of intensity. They maintain that the appearance of one or other of these morbid states after a surgical operation is dependent in part upon differences in the constitutional condition of their patients, and, moreover, that these forms of disease are further linked to one another by numerous intermediate states. This point of view has been both strengthened and extended by some of the experimental researches of Dr. Burdon Sanderson. He found that the subcutaneous injection of different portions of the same inflammatory product, executed at the same time, would often produce quite different effects upon different animals of the same species. In the one a typical septicæmia proved rapidly fatal, in another a slower pyæmic process was established, whilst in a third animal the still more chronic process of so-called tuberculosis was set up. Here again we seem to get out of the region of speculation into that of fact. See *Trans. Path. Soc. of London*, 1872, pp. 303-308.

The term 'correlation' is only applicable to communicable diseases, otherwise its leading signification, namely, convertibility, could not be fulfilled. Hence it is that, though very many diseases may arise from the operation upon different individuals of some common cause (such as exposure to cold), the maladies which may result from such a cause no one would think of speaking of as correlated.

H. CHARLTON BASTIAN.

**CORROSIVE SUBLIMATE, Poisoning by.**—See MERCURY, Diseases arising from.

**CORYZA** (κόρυζα, a running from the head).—A synonym for nasal catarrh. See CATARRH.

**COUGH.**—SYNON.: *Tussis*; Fr. *Toux*; Ger. *Husten*.

**DESCRIPTION.**—The *act of coughing* consists in one or more abrupt forcible expirations, preceded by contraction of the glottis. First a deep inspiration is taken, the glottis is closed for a moment, and then

it is opened by the pressure of the air forced out by the combined action of the thoracic and abdominal expiratory muscles. With the air thus suddenly expelled, any foreign matter that may be in the larynx or bronchi is driven into the pharynx or the mouth.

**ÆTIOLOGY.**—The immediate cause of cough is the presence of an irritant, mechanical or sympathetic, affecting the surface of the air-tubes or the nerves that supply them, and it is the object of the cough to remove this source of irritation.

The sensibility of the respiratory surfaces is greatest at its commencement—the glottis being an ever-watchful janitor. It may be increased by congestion or inflammation, or by the continued act of coughing. Even the mere inhalation of cool or dry air may, in asthma or bronchial congestion, be sufficient to excite cough. The result of the irritation is to increase the natural secretion, and to alter its characters. See EXPECTORATION.

Cough may be due to numerous reflex causes, such as gastric irritation, ear-disorder, aneurysmal, glandular or other pressure on the vagus, recurrent, or sympathetic nerves. The act may also be caused by a long uvula or enlarged tonsil; a granular state of the pharyngeal or laryngeal mucous membrane; polypi or other foreign bodies in the larynx, trachea, or even in the external auditory meatus; various affections of the bronchial tubes—for example, undue dryness, hyperæmia, alteration in the quality or quantity of the bronchial secretion, or inflammatory affections; inflammation of the lung or pleura; or tubercle, cancer, or other growths in or near the lung.

**DIAGNOSIS.**—Cough is not a disease to be treated, but a symptom to be traced to its source. An inspection of the pharynx and larynx, and a physical examination of the chest, will generally suffice to detect the cause.

The character of the cough is often quite pathognomonic—*e.g.* the 'whoop' of whooping cough; the 'bark' of hysteria; the catching, painful cough of pleurisy; the slight 'hack' of early phthisis, and the equally distinctive cough of advanced phthisis with laryngeal ulceration; the tearing cough of empyema threatening bronchial fistula; the loud clanging cough due to pressure on the trachea or laryngeal nerves; the spasmodic, suffocative cough of asthma.

The 'tightness' or 'looseness' of cough, indicating the absence or presence of secretion, is a valuable guide in diagnosis and treatment.

The *absence of cough* is no proof of the absence of serious lesion; thus, while the presence of a few granulations in the lung is often productive of incessant and uncontrollable cough, long-continued destructive disease may exist without it.

**TREATMENT.**—Before prescribing for a

cough it is of course essential to ascertain its cause; and the simplest and most innocuous remedies should be first used. The routine treatment of cough by sedatives is highly injurious. The secretions which ought to be removed are thus locked up, and the irritation, which would have been transient, becomes established.

If the tonsils are found much enlarged, or the uvula pendulous and irritating the epiglottis, caustics or the guillotine will remove the evil. If a granular state of the pharyngeal membrane exists, dependent on torpid or engorged abdominal viscera, gout, or hepatic obstruction, it may be treated by local astringents and general deobstruents.

A lax or congested state of the laryngeal membrane, due to overwork of voice, or the undue direction of attention to the vocal apparatus (clergyman's sore-throat), is best treated, according to the writer's experience, by the local application of a solution of zinc sulphate—ten grains to an ounce of water, or of iodine dissolved in spirit and olive oil. Undue dryness, simple hyperæmia, or hyperæsthesia of the respiratory mucous tract, may often be relieved by the act of sipping and slowly swallowing cold water, or the decoction of Iceland moss, fruit lozenges, gum arabic, liquorice, or linseed tea. Sucking ice or inhaling steam is very often all that is needed. In the early stage of catarrhal sore-throat, chlorate of potassium in crystal, or in the form of lozenge, used in moderation, should not be neglected. The use of glycerine of tannin, or nitrate of silver dissolved in glycerine (half a drachm to one ounce), is of more service in relaxed throat than alum or tannin gargle; indeed, the free use of well-selected lozenges has rendered the employment of gargles well-nigh obsolete. The former can be constantly, the latter but seldom applied.

*Medicinal treatment.*—If it is desired to increase the fluidity of the secretion, squill or ipecacuanha may be used, or, better still, tartar emetic in small doses, which is best given in effervescence with carbonate of ammonium and citric acid. It must not be forgotten that syrups and nauseating expectorants are apt to do harm by enfeebling or disturbing digestion. Tincture of aconite, in three-drop doses, is often of value in allaying irritable cough, especially when fever is present. Gelsemium is a more recent remedy for the same purpose. Of the direct sedatives, morphine is the most valuable; it proves of service in very small doses,  $\frac{1}{12}$  gr. in a lozenge being often adequate. Conium, with or without morphine, suits some persons; hydrocyanic acid still more; and Indian hemp is also of value. The bromides, in combination with chloral, have gained great repute; the latter should be given with caution. The power of the bromide of ammonium in allaying spasmodic cough is re-

markable. An emetic of ipecacuanha, sulphate of zinc, or mustard may be useful in relieving cough, by expelling secretion when this has accumulated in large quantity. If cough causes vomiting, food should be taken in small quantities, fluids should be limited, and a little capsicum or spiced brandy 'stays the stomach.'

*External applications.*—The use of counter-irritants must not be neglected. In the inflammatory stage of bronchitis, for instance, linseed and mustard poultices, and, in the later stages, iodine, are of great use; and in some cases the application of a small blister or vesicating fluid is a remedy not to be forgotten.

*Inhalations.*—Infusion of hop as an inhalation is a useful calmative; iodine is indicated in relaxed conditions in strumous subjects. Chloroform (10 to 15 minims) mixed with eau de Cologne, and inhaled from a handkerchief, is useful in other cases. By means of the spray-inhaler, many non-volatile preparations may be applied to the respiratory passages. A solution of carbonate of sodium is very useful in liquefying tenacious secretion. Tannic acid, alum, perchloride of iron, and nitrate of silver, are all valuable. Of sedatives, henbane, conium, camphor; and of antiseptics, sulphurous and carbolic acids, are serviceable as inhalants. The vapour of tincture of iodine, 15 drops to 2 ounces of water, in the steam draught inhaler, is often useful. In chronic granular disease of the pharyngeal and laryngeal mucous membranes, the sulphurous waters of Aix-la-Chapelle, Aix-les-Bains, and St. Saviour in the Pyrenees, when inhaled in an atomised state, are of distinct service.

Patients may be *taught how to cough* as follows: Try to suppress the inclination, until the secretion that causes the cough is within reach, then take a deep and deliberate inspiration, and the accumulated phlegm is removed at a single effort. By inhaling steam from a hot sponge or a basin of boiling water on first waking from sleep, the inspissated secretion, which is apt to be difficult to move, may be easily loosened and expelled. An ipecacuanha lozenge may serve a similar purpose. E. SYMES THOMPSON.

**COUNTER - INDICATION.** — See CONTRA-INDICATION.

**COUNTER-IRRITANTS.**—SYNON.: Fr. *Contre-stimulants*; Ger. *Gegenreizmittel*.

**DEFINITION.**—The term 'counter-irritation' implies any irritation artificially established with a view to diminish, counteract, or remove certain morbid processes which may be going on in a more or less remote part of the system. The substances employed in establishing this state are called counter-irritants, and may be classified as follows,

according to the degree of their action:—  
 1. *Rubefacients*. 2. *Epispastics, vesicants, or blistering agents*. 3. *Pustulants*.

Although some therapeutists have of late been disposed to question the value of counter-irritants, on the theoretical ground of inability to explain their mode of action, yet there is not wanting evidence, both from clinical observation and physiological experiment, that irritation in one part of the body may affect the functions and nutrition of other parts. That stimulation of the vessels of the surface can influence decidedly the circulation of deeper parts has been demonstrated by Dr. Brown-Séguard; for he found that irritation of the skin of the back, over the kidneys, caused a contraction of the arteries supplying those organs. Zülzer found that when cantharides collodion was painted over the back of a rabbit for fourteen days the vessels underneath the skin were congested, whilst the deeper parts, including the lungs, were pale and anæmic. From these experiments we can understand how a blister may relieve a sudden internal congestion in the lungs or brain, and how it may act in restoring tone to dilated and paralysed capillaries.

*Revulsion* and *derivation* are both examples of counter-irritation. In the first, the induced morbid action is set up in a part remote from the primary disease, as when mustard poultices are applied to the feet in an attack of apoplexy; in the second, derivative action is set up in the neighbourhood of the primary malady, as when a blister is placed on the back of the neck for the relief of cerebral disorder.

**1. Rubefacients.**—**ACTION.**—These remedies, applied to the skin, produce local warmth and redness from increased flow of blood in the cutaneous vessels. The local hyperæmia thus induced subsides gradually on ceasing to employ the rubefacient; but sometimes, when the action of this has been prolonged, the epidermis may peel off, and more or less local soreness remain. Rubefacients are usually quick in action; their local after-effects are trifling; and they may, therefore, be applied without injury over a large extent of surface.

**ENUMERATION AND APPLICATION.**—Examples of rubefacients are found in Ammoniacal liniments or embrocations; Mustard plasters and the Compound Liniment; Volatile Oil of Mustard; Oils of Turpentine and Cajuput; and Iodine. Hot water is at times applied on a sponge or flannel to produce a speedy counter-irritant and derivative effect in relieving sudden internal congestion and spasm, as in the early stage of croup, laryngitis, and laryngismus stridulus. The Cataplasma Sinapis, or mustard poultice, is a useful and rapidly acting rubefacient in inflammation, spasm, and neuralgic pain. Sir Alfred Garrod recommends a very useful

sinapism, made by mixing 10 minims of volatile oil of mustard with 1 oz. of spirit of camphor, and sprinkling this on impermeable piline. Rigollot's mustard leaves, or the Chartæ Sinapis (B.P.), applied to the skin, produce a speedy rubefaction of the surface. Linimentum Sinapis Compositum is also a very active rubefacient. Vinegar should not be added to mustard poultices; but by mixing some oil of turpentine or a little powdered capsicum in a mustard poultice, its rapidity of action as a stimulant and rubefacient can be greatly increased. Where, on the other hand, a gentle stimulation with warmth and moisture on the surface are desired, as in some cases of pneumonia, a linseed-meal poultice may be used with its surface sprinkled lightly over with mustard meal. Generally twenty minutes is as long as an ordinary mustard poultice can be safely borne on the skin. In persons who have a very delicate skin, a layer or two of muslin should be placed between the mustard application and the surface of the body. In applying mustard poultices to those who are unconscious of pain, caution is necessary, for it has happened that the poultice being left on for a long time has produced dangerous ulceration and sloughing of the surface. A mustard foot-bath is at times employed with a view to a revulsive and counter-irritant effect. To prepare a mustard bath, two tablespoonfuls or more of mustard should be tied in a cloth and agitated well with cold water; then hot water may be added to make the bath. It is found by experiment that cold water extracts the active principle or volatile oil of mustard far better than very hot water does.

**USES.**—Rubefacients are used in chronic inflammation and irritation of the mucous surfaces, as in bronchitis, and irritation about the air-passages. Troublesome cough, in cases of phthisis, is often relieved by applying tincture of iodine, or acetic acid and turpentine liniment, to the chest. Rubefacients are of service in removing lingering irritation about a joint, their use also tending to promote the absorption of chronic thickening or effusion in the joint; but friction with a rubefacient liniment over a joint must not be employed till all active inflammatory action has entirely ceased. Various degrees of persistent counter-irritation may be maintained by applying, after the skin has been well cleansed with soap and water, the Emplastrum Picis or Emplastrum Calefaciens of the Pharmacopœia. A mustard plaster applied to the nape of the neck has proved useful in cases of irritable brain with sleeplessness. The same application made to the foot or great toe is a valuable revulsive where gout attacks more important organs. A mustard plaster has the advantage over a blister in rapidity of rubefacient action; and, from the sharp pain caused, the mustard plaster is preferable when it is a matter of

moment to rouse one who is in a state of lethargy or torpor from narcotic poisoning by opium, or alcohol, or from coma in the course of a fever. Where we wish to exercise a prolonged action over chronic inflammation in an organ, we should use a blister rather than a sinapism.

**2. Vesicants, Epispastics, or Blistering Agents.**—**ACTION.**—A blister acts primarily as a rubefacient and powerful stimulant to the cutaneous vessels. The papillæ of the skin become reddened and raised; minute vesicles soon appear on the elevations; and these, gradually coalescing, form a bleb, or large vesicle, between the true skin and epidermis, containing an albumino-fibrinous fluid.

**ENUMERATION AND APPLICATION.**—The agent most commonly employed for blistering purposes is the *Cantharis* or Spanish fly; but there are others that have been used for a similar object. Glacial Acetic Acid applied to the skin produces intense redness and pain, with rapid vesication, but its action may extend too deeply as a caustic, and cause a troublesome sore. *Liquor Ammoniz* dropped on a piece of lint, applied to the skin, and covered with a watch-glass, very soon causes redness and rapid vesication in most persons. This is a good way of raising a blister when it is desired to apply powdered morphine endermically to relieve severe pain. The *Liquor Epispasticus* of the *Pharmacopœia*, applied with a brush, soon raises a blister on the surface. *Blistering Collodion* is used for a similar purpose, but is slower in action.

The application of blisters should not be made directly over an inflamed part. There is some evidence to show that a strong stimulus applied very near an inflamed organ may increase the paralytic dilatation of its capillaries, and so add to the disease. Blisters should not be applied where the skin is loose, nor over any prominence of bone, nor to the breast during pregnancy. It should moreover be borne in mind that the cantharidine of a blister may be absorbed by the skin, and act on the kidneys, producing strangury and bloody urine. This accident may be obviated by sprinkling powdered camphor over the blister before placing it on the skin, or a thin piece of silver paper may be interposed. In persons of feeble vitality, a blister left on for too long a time has been known to induce dangerous sloughing.

When vesication is specially desired, there is no need to leave the blister on for twelve hours or more, for it may be removed at the end of six or eight hours, and a warm linseed poultice applied. If the blister be opened, which is best done by pricking the most dependent part with a disinfected needle, sweet oil and cotton-wool is the best dressing. The practice of maintaining a blister as a running sore or *exutoire*, by applying irritating oint-

ments, is not often resorted to now. The process causes great pain and exhaustion of the system, and is one rather of depletion than of counter-irritation. In the case of children, blisters should be used with caution, being kept on for about one hour or till the skin is well reddened, when they should be replaced by a poultice. It is well not to open the blister, as the effused serum forms the best dressing covered with cotton-wool. By following this plan the child is saved much worry and pain.

**USES.**—In its primary effect a blister acts as a local stimulant, but when it remains on long enough to produce extensive vesication and discharge of serum, it acts as a depletive and depressing agent. This primary and secondary action of blisters has been much insisted on by the late Dr. Graves of Dublin, who found great benefit in cases of fever with apathy and prostration from the application of *flying blisters* to various parts of the surface. Thus a blister over the præcordial region, kept on for about one hour, and then removed, was observed to rouse and stimulate a flagging heart. In other cases the flying blister might be placed at the chest or back, or else behind the head on the neck. Care should be taken not to leave the blister on long enough to cause actual vesication, and the size of the blister should be fairly large.

Vesication by a blister is of service in many brain-affections attended with congestion and tendency to serous effusion, such as in the chronic forms of hydrocephalus, and non-tubercular meningitis. In hysterical paralysis narrow strips of blister placed completely round the affected limb have proved curative. A strip round the throat may cure nervous aphonia. A strip of blister one inch wide may possibly sometimes stay the spread of erysipelas along a surface. In cases of pleuritic or pericarditic effusion the repeated application of blisters to the chest-wall is of manifest advantage. In effusions into joints (*hydrarthrosis*) blisters aid absorption; and it has seemed to the writer that absorbent remedies, such as iodide of potassium, often begin to do good as soon as a blister appears to have once set the absorptive process in action. In the joint-affections of acute rheumatism, 'the blister treatment' has attracted notice. Armbands and wristlets of blister-plaster are applied close to the inflamed joints during the fever, and the serous discharge from the blister is kept up by means of linseed-meal poultices.

In the obstinate acid vomiting of gouty patients, a blister over the epigastrium often gives relief. Some forms of neuralgia, as for example pleurodynia, may yield to a blister over the seat of the pain. At times obstinate pleurodynia, or mastodynia, can be relieved by flying blisters applied in the vertebral groove on the affected side, where a tender

spot can often be detected on pressure. Blisters should be avoided in cases of renal and vesical inflammation, as the absorption of the cantharidine may increase the mischief.

**Counter-irritation by heat.**—The skin can be rapidly blistered by applying a hammer—'Corrigan's hammer'—a small flat iron heated in a spirit-lamp or boiling water. The skin is tapped for a few seconds with the hammer, just to induce redness of the part. In some forms of rheumatism, neuralgia and spinal weakness, this practice has been followed by satisfactory results. Vesication of the skin by the *ferrum candens*, or hot iron, has been used in chronic joint-disease.

**Moxas.**—Moxas were used for the purpose of causing severe counter-irritation. European moxas were made either with cotton-wool soaked in solution of nitrate of potassium, or of the pith of the sunflower, which naturally contains this salt. A wet rag was placed on the skin; in the centre of this was a hole in which the lighted moxa was placed, which gradually burned down to the skin and produced an eschar, which in due time separated by suppuration. In spinal affections, and in some forms of paralysis of the sensory and motor nerves, moxas are said to have done good; but their application is very painful, and now they are seldom employed.

**3. Pustulants.**—ACTION.—The agents belonging to this class of counter-irritants produce a pustular eruption on the part to which they are applied, and their use is not recommended.

ENUMERATION AND APPLICATION.—Among pustulants may be placed Croton Oil, Tartarated Antimony, and strong solution of Nitrate of Silver. When croton oil is applied to the skin, it acts as an intense irritant, producing an eruption which is at first papular, but very soon becomes pustular. The oil is best employed in the form of the Linimentum Crotonis of the Pharmacopœia. Tartarated Antimony in the form of the Ointment, or in hot aqueous solution, is a powerful counter-irritant, producing pustules which resemble those of variola. When applied thus it may, by becoming absorbed, induce symptoms of gastro-enteritis. It should not be applied to parts usually uncovered, as the pustules leave marks behind them; and under all circumstances the remedy, being a painful one, must be used with caution. Strong solution of nitrate of silver will produce pustulation, but it is seldom employed for this purpose.

**Issues.**—Issues have long been used as counter-irritants. An issue is formed by placing on the skin a piece of adhesive plaster, in a hole in the centre of which a fragment of caustic potash is inserted. The caustic causes an eschar, and when this has come away, an issue-pea is placed in the

cavity left by the eschar; this pea acts as a foreign body, and keeps up suppuration. One drachm of pus may be discharged daily by an issue; more than this is too great a drain on the system. An issue requires to be dressed daily, and when it has been long open and running it must not be healed too suddenly. Issues over the spine have been found useful in chronic spinal disease; and in some chronic brain-affections, with hyperæmia and congestive tendency, an issue in the back of the neck or in the arm is of service, but is not now much used.

**Setons.**—A seton is made by passing a narrow-bladed knife under a fold of skin and then carrying a few silk threads through the incision by means of a probe or long needle. The threads remaining in the wound prevent it from healing, and maintain a free purulent discharge. Setons are used for the same purposes as issues, and they have proved useful in certain intractable forms of headache—the seton being inserted in the skin of the neck. Setons have been used in cases of cystic bronchocele with thickened walls; and, as counter-irritants, in chronic inflammation of the bladder and uterus; in chronic skin-diseases of an obstinate character; in inflammations of the eye, with ulceration of the cornea; and in the early stages of pulmonary phthisis.

In acute affections issues and setons are never employed, and they should not be placed over any part where there is much movement, as a troublesome sore may be the result. It is necessary to bear in mind that issues, setons, and pustulants are, like blisters, when kept on long enough to induce serous discharge, of the nature of evacuations. They carry off nutrient material from the blood, and therefore are more or less depressing and exhausting to the system, and their repeated or protracted employment will tend to induce the irritative fever of debility.

JOHN C. THOROWGOOD.

**COUP DE SOLEIL** (Fr.).—A synonym for sunstroke. See SUNSTROKE.

**COW-POX.**—See VACCINIA.

**COXALGIA** (*coxa*, the hip; and *algos*, pain).—Pain in the hip-joint. See JOINTS, Diseases of.

**CRACKED-METAL** or **CRACKED-POT SOUND.**—SYNON.: Fr. *Bruit de pot fêlé*.—A peculiar sound elicited by percussion, and resembling that emitted on striking a broken jar or a metallic vessel. See PHYSICAL EXAMINATION.

**CRADOCK**, in Cape Colony.—See AFRICA, SOUTH.

**CRAMP.**—SYNON.: Fr. *Crampe*; Ger. *Krampf*.—This name is applied to certain painful varieties of tonic spasm. In its most familiar form it affects the calves of the legs,

coming on principally at night, on the occasion of some slight movement of these parts. The affected muscles, mostly on one side, contract with such energy as to give rise to a board-like rigidity, together with sensations of an agonising character. The attack rarely lasts more than a minute or two, though it may more or less speedily recur. It is perhaps best cut short by a vigorous but steady voluntary contraction of the opposing extensor muscles of the foot. Where it is more obstinate than usual, firm pressure around the thigh or upon the great sciatic nerve sometimes gives relief. Cramp is often associated with some irritation of the stomach or of the intestines, especially in children or delicate nervous persons. In this way it is produced not infrequently when arsenic in medicinal doses has been continued for some time, and is beginning to exert some slightly poisonous effect upon the system. In a more general form it often occurs, to a marked extent, in cholera. Localised, painful, cramp-like contractions of muscles may also be due to irritation of anterior root-fibres, either in their intra-medullary or extra-medullary course. Other forms of painful spasm are by no means common, if we except colic. See SPASM; and THOMSEN'S DISEASE.

H. CHARLTON BASTIAN.

**CRANIOTABES** (*cranium*, the skull; and *tabes*, thinning).—A morbid condition of the cranium in children, consisting in spots of local thinning of the occipital, parietal, and (rarely) the frontal bones, as well as in general abnormal flexibility of the osseous tissue. See SKULL, Diseases of.

**CREPITANT** (*crepito*, I make a noise). When applied to a body, this word signifies that it is capable of yielding the sensation or sound of crepitation. It is also associated with a râle, to indicate a peculiar character which it possesses. See PHYSICAL EXAMINATION.

**CREPITATION** (*crepito*, I make a noise).—A sensation or sound of crackling. It may be observed in morbid states of the bones, joints, or subcutaneous tissue; but the term is more frequently applied to a physical sign connected with the lungs. See PHYSICAL EXAMINATION.

**CRETINISM** (*crétin*, Swiss *patois* for *chrétien*, a Christian).—SYNON.: Lat. *Cretinismus*; Fr. *Crétinisme*; Ger. *Cretinismus*.

DEFINITION.—A condition of idiocy arising from endemic causes, associated with imperfect development and deformity of the whole body, varying however in degree.

This condition of physical and mental degeneracy is not limited to any nationality. It obtains in the great mountain-chains of Europe, Asia, and America. In Europe it

is met with in the valleys of Switzerland, Savoy, and Piedmont; and it abounds in the neighbourhood of Salzburg, Styria, and the Tyrol. It is less frequently met with in the Pyrenees and in the valleys of the Auvergne in France. Even in England it has been met with in various parts, among others in the dales between Lancashire and Yorkshire. Although more frequently met with in valleys, it is not unknown on plains which are subject to inundations.

ÆTIOLOGY.—The conditions for the development of cretinism are hereditary predisposition; the action of deteriorating influences on the parents, such as unwholesome dwellings and non-nutritious diet; and accidental causes operating on the infant during the period when its physical and intellectual life are developing. The last-named causes are atmospheric and possibly geological conditions, peculiar to special localities. Humidity of the soil and air in valleys where there is little interchange of the atmosphere, and the existence of magnesian limestone in the soil, are probably the most potent factors. Cretinism is not met with as an endemic disease on elevated plateaux, nor in cold countries where sudden changes of temperature are uncommon. Goitre is a frequent accompaniment of cretinism, and would appear to be developed under the same conditions. The cases of cretinism met with in England present features which are indicative of a scrofulous origin. There is a condition of idiocy associated with arrest of growth and development at the period of first dentition, not infrequently met with in England, which has been termed *sporadic cretinism*. Some of these cases have been traced to alcoholism on the part of the progenitors, and are usually associated with an absence or atrophy of the thyroid body, and with the development of loose fatty tumours in the supra-clavicular spaces. They remain permanent children, both physically and mentally. They have a strong sense of the ridiculous, and are fond of exciting ridicule in others by their grotesque facial expressions. There is reason to believe that children become cretinoid when taken to reside, at the period of their early development, in localities where the disease is markedly endemic. There are numerous well-attested instances of healthy women living during their pregnancy in cretinic districts bringing forth cretinoid children, who, removing from such localities, propagate healthy children. By far, however, the greater number of cretins arrive at their helpless condition by successive steps of degeneracy in their ancestors. It has been thought that cretinism is due to premature ossification of the cranial sutures, especially of the pheno-basilar suture; and that this is caused by drinking water largely charged with lime. It is impossible, however, to regard this premature ossification, when it

does occur, as other than one of the outcomes of the malady, not its cause. Moreover, there are numerous examples where the synostosis is deferred instead of being premature.

**ANATOMICAL CHARACTERS.**—Pathological anatomy shows that the bones of the cranial vault are thickened and without diploë. The basilar groove is generally wanting. The foramina for the passage of arteries and nerves are somewhat smaller than natural. The occipital fossæ are flatter than usual, as if the flattening had resulted from a compression of the cranium from above downwards. Every variety of deformity of the cranium is met with of the brachycephalic type. The brain is usually small, unsymmetrical, pale, and infiltrated with serum. Premature synostosis is occasionally met with at the spheno-basilar suture, and with it a rectangular form of the base of the skull; this, however, cannot be regarded as a constant condition.

**DESCRIPTION.**—The degrees of cretinism are numerous. A residence in one of the valleys where this affection exists, enables one to trace the various steps of degeneracy, commencing with those who are taking part in the industrial life of the valley, down to the helpless individuals who are leading only a vegetative existence.

The typical cretin presents a very marked physical conformation. He is stunted in growth, rarely reaching five feet in height. His skin is of a tawny yellowish hue, thickened and wrinkled; and looks as if too large for the body. There is also a great increase of subcutaneous areolar tissue. His tongue, large and thick, with hypertrophied papillæ, always displays lessened power of co-ordination; and often hangs from the mouth. The mouth is partly open, margined by thick fissured lips, and with the saliva running over the chin. The face is large; the lower jaw is drooping, and its angle obtuse. The eyes are often affected by strabismus, obliquely placed, and small; and the lids are commonly puffy. The belly is pendulous from the laxness of the skin. The lower limbs are generally short and deformed, and the gait is waddling. The head is deformed, the forehead retreating, the top flat, and the occipital region ill-developed. The cranium is brachycephalic. The nose is broad and flattened. Puberty is often delayed to the twentieth year. The mammæ in the female are large and pendulous; the same remark applies to the genitals in the male. The intellectual faculties are imperfectly developed. The cretin is often unable to speak, and his hearing is frequently defective. The affection is usually associated with more or less enlargement of the thyroid gland. His viability is low, few living beyond thirty years of age. The sexual functions are abnormal; masturbation is

frequent; and the subjects of cretinism are often im potent.

**DIAGNOSIS.**—The diagnosis of cretinism may be made in childhood, from the slowness of the development of the body, the stupid expression, the postponement in the evolution of the teeth, and of the ossification of the fontanelles and sutures, the tawny yellow colour of the skin, the thick and goitrous neck, the slaving, and the delay of speech and of walking.

**TREATMENT.**—This consists in removing the child as early as possible from the circumstances which have produced the disease. He should be taken to a locality where the soil is dry and porous, and should have frequent baths with friction to the surface of the body. The diet should be of the most nutritious kind—a diet into which animal food largely enters. The administration of cod-liver oil and of the lacto-phosphates of lime and iron is indicated. Early education should be commenced as to habits of cleanliness, followed by systematic physical exercise of the various muscles. All intellectual advancement must be sought for through the improvement in every way of his physical condition. The lower animal life may thus be supplemented, if earnest efforts are used, by increased capacity for rational enjoyment, and a more or less useful existence.

J. LANGDON-DOWN.

**CRIME, IRRESPONSIBILITY FOR.**—**HISTORICAL SUMMARY.**—A medical opinion as to the condition of an accused person is often necessary in order to determine whether he or she can be held accountable for criminal acts. Such an opinion generally depends on the presence or absence of insanity, or on the connexion which may be traced between this mental condition and the act in question. In the article on legal insanity it is explained that it is only within a comparatively recent period that insanity has been admitted as an excuse for crime, except in those comparatively rare cases in which, as Justice Tracey expressed it in 1723, a person does not know what he is doing, 'no more than an infant, a brute, or a wild beast' (see *INSANITY, LEGAL*). This view fairly represents the state of public and of legal opinion until the later years of the eighteenth century. The subsequent enlightenment of the public mind did not receive juristic expression until the trial of Hadfield in 1800, when Erskine first enunciated the doctrine, that 'delusion where there is no frenzy or raving madness is the true character' of such insanity as implies irresponsibility. The most important case in the history of this question was that of Bellingham, who was executed in 1812 for shooting Mr. Spencer Perceval. In this case Lord Chief Justice Mansfield said, that if a person labouring under mental derangement were capable in other respects of distinguish-

ing right from wrong, 'he could not be excused for any act of atrocity which he might commit.' 'It must be proved beyond all doubt,' he added, 'that at the time he committed the atrocious act he did not consider that murder was a crime against the laws of God and nature.' The trial of MacNaughton in 1843 for the murder of Mr. Drummond led to the most authoritative statement of the law which has ever been obtained in this country. MacNaughton was acquitted on Chief Justice Tindal's direction that the point for the jury to consider was whether 'at the time the act was committed' the accused 'had that competent use of his understanding as that he knew that he was doing by the very act itself a wicked and wrong thing.' The general application of this doctrine would have greatly enlarged the area of irresponsibility, and its enunciation at that time produced considerable surprise and even consternation. The matter was indeed regarded as so urgent that the House of Lords immediately ordered a series of questions to be laid before the fifteen judges with the view of settling the state of the law. In the answers to these questions it was in substance laid down that, to entitle an accused party to acquittal on the ground of insanity, it is necessary that he be either of diseased mind, and at the time he committed the act not conscious of right or wrong; or, that he be under some delusion which made him regard the act as right. But this statement has been far from effecting a final settlement of the question.

Most writers on medical jurisprudence have insisted that the real criterion of responsibility is the freedom of the will, or the power of the individual to control his actions. This has been more or less advocated by Esquirol, Marc, Ray, Pagan, Jamieson, Mittermaier, and von Krafft-Ebing. Esquirol dwells strongly on the importance of the freedom of the will. Ray includes it in the comprehensive statement which has received the approval of so many medical jurists. 'Liberty of will and action,' he says, 'is absolutely essential to criminal responsibility, unless the constraint upon either is the natural and well-known result of immoral or illegal conduct. Culpability supposes not only a clear perception of the consequences of criminal acts, but the liberty, unembarrassed by disease of the active powers which nature has given us, of pursuing that course which is the result of the free choice of the intellectual faculties.' Pagan observes that the 'loss of control over our actions, which insanity implies, is that which renders the acts which are committed during its continuance undeserving of punishment.' Jamieson puts the question: 'Had the lunatic at the time of committing the deed a knowledge that it was criminal, and such a control over his actions as ought, if it existed, to have hindered him from committing it?' Dr. Taylor says: 'The power which

is most manifestly deficient in the insane is generally the controlling power of the will'; and he expresses the opinion that 'we have here a fair criterion on which responsibility or irresponsibility may be tested.' Dr. Bucknill's view is substantially the same. 'Responsibility,' he says, 'depends upon power, not upon knowledge, still less upon feeling. A man is responsible to do that which he can do, not that which he feels or knows it right to do. If a man is reduced under thralldom to passion by disease of the brain he loses moral freedom and responsibility, although his knowledge of right and wrong may remain intact.' The latest German code puts responsibility upon the same basis. 'An act is not punishable,' according to it, 'when the person at the time of doing it was in a state of unconsciousness; or of disease of the mind, whereby free volition was prevented.' Mittermaier and von Krafft-Ebing sanction the attempt to render the meaning of 'free volition' more definite by describing it as made up of *libertas judicii* and *libertas consilii*—freedom of judgment and freedom of choice. Casper somewhat obscurely defines criminal responsibility as 'the psychological possibility of the efficacy of the penal code.' Mr. Balfour Browne, a recent writer, gives as the best definition 'a knowledge that certain acts are permitted by law, and that certain acts are contrary to law, and, combined with this knowledge, the power to appreciate and be moved by the ordinary motives which influence the actions of mankind.' Dr. Guy thinks that every person who is insane must be regarded as wholly irresponsible, and that the law of England ought to be assimilated to that of France in the declaration that: 'Il n'y a ni crime ni délit lorsque le prévenu était en état de démence au temps de l'action.' Mr. Warren, on the other hand, suggests that a person should not be held irresponsible unless he were as 'unconscious of his act as a baby.' Dr. Maudsley and others hold that the determination of responsibility in cases where insanity is alleged depends on whether a connexion can or cannot be traced between existing disease and the act.

Insanity has been pleaded as an excuse for acts of theft; but such cases are rare, and never occur except where the social position of the accused adds importance to the decision. Indeed it may almost be said that the plea is never raised except in order to avoid capital punishment. Hence it is, that in the discussions which have arisen the question has been intimately associated with the law of murder and homicide. A special inquiry into the state of this law by a Committee of the House of Commons<sup>1</sup> has consequently given occasion to the enunciation of important views as to the legal relations of

<sup>1</sup> Report of Select Committee of the House of Commons on the Homicide Law Amendment Bill, July 21, 1874.

insanity and responsibility. Evidence was furnished to the Committee by Lord Chief Justice Cockburn, Baron Bramwell, Mr. Justice Blackburn, and Sir James Fitz-James Stephen. The immediate object of the Committee was to examine a bill drawn by Sir James Stephen for the codification of the law of homicide. In the clause of the bill which deals with the relations of disease and responsibility, homicide is stated to be 'not criminal if the person by whom it is committed is at the time when he commits it prevented by any disease affecting his mind—(a) from knowing the nature of the act done by him, (b) from knowing that it is forbidden by law, (c) from knowing that it is morally wrong, or (d) from controlling his own conduct.' But it is stated to be 'criminal, although the mind of the person committing it is affected by disease, if such disease does not in fact produce one of the effects aforesaid in reference to the act by which death is caused, or if the inability to control his conduct is not produced exclusively by such disease.' It was, however, proposed in the bill that, 'if a person is proved to have been labouring under any insane delusion at the time when he committed the homicide, it shall be presumed, unless the contrary appears or is proved, that he did not possess the degree of knowledge or self-control hereinbefore specified.' That is to say, where delusion exists, the burden of proving moral capacity would be shifted, the prosecutor having to prove its existence, instead of the accused having to prove its absence. The opinions elicited during the inquiry showed that the law is regarded by legal authorities as being at present too uncertain in its operation, and as failing to recognise some of the most important elements in the question. The divergent character of the recommendations which were made showed, however, that legal opinion is much divided, not only as to the proper relations of insanity and crime, but also as to the essential elements of responsibility. In the meantime, therefore, the statements of the fifteen judges after the MacNaughton case remain the chief exposition of the English law where insanity is pleaded in excuse for crime.

PRESENT STATE OF THE QUESTION.—It is necessary, in order to justly appreciate the present aspect of the subject, thus to trace its more recent history, and it might be useful to present an estimate of the comparative value of the several tests or criteria which have been proposed for the determination of cases in which insanity has been alleged. These criteria may be broadly summarised in the following six propositions. According to one view a person should be held irresponsible for an act if at the time of committing it (1) he laboured under insanity of any kind or degree; according to another, if (2) he laboured under delusion;

or (3) if he was ignorant of right and wrong; or (4) had not power to appreciate and be moved by ordinary motives; or (5) had lost the controlling power of the will; or (6) if the act is traceable to, or its nature has been determined by mental disease affecting the agent. The last of these views is the only one to which fatal objection may not be raised, both on the theoretical and practical sides. The others are all too vague to be of much advantage; and they rather tend to introduce new difficulties than to remove those already existing. The proposition therefore which seems to approach nearest to a solution of the difficulty is that irresponsibility must be admitted whenever the act is traceable to, or its nature is determined by mental disease affecting the agent. It will of course be understood that under such a rule the term 'mental disease' must be held to include both congenital and acquired disorders; arrest of development being as much a morbid condition as functional or structural change. This view of the subject may not be ultimately accepted in the precise terms of the proposition here given; but the principle on which it rests seems to afford the only safe basis upon which we can go. As has already been shown, it has not hitherto been regarded in this light by the majority of the judges; but there have been indications of late years that judicial views are tending in that direction. The late Lord Wensleydale and others have given sanction to the principle in their judicial statements. And the late Lord Justice-General of Scotland (Ingis) gave definite expression to it in one case (*Brown*, Sept. 1866). He told the jury that the main question was 'whether the prisoner was in such a state of insanity at the time, as not to be responsible for the act which he had committed;' and in order to constitute such insanity he said that 'it must be clearly made out that at the time of committing the act the prisoner was labouring under mental disease in the proper sense of the term, and that that mental disease was the cause of the act.' In America the doctrine has been frequently acknowledged, but never more fully and tersely than by Judge Doe, of New Hampshire (*State v. Pike*), who comprehensively defined the medical relations of both criminal irresponsibility and civil incapacity, when he stated that a 'product of mental disease is neither a contract, a will, nor a crime.' One important point is to prevent persons from being punished for actions which are the direct outcome of pathological processes. But it is of equal importance to avoid the adoption of a principle which would make the existence of slight mental irregularities incompatible with responsibility. There does not appear to be any danger of this in acting on the principle which is here enunciated. For it lies in the very nature of the cases in which

the doctrine could be applied, that the condition to which it is proposed that irresponsibility should be attached must be one which is known to exhibit itself in acts of serious and even criminal character. If the trained observer of disease is able to recognise in an act—which is ordinarily followed by severe punishment—a direct result or a characteristic feature of a morbid process, of the existence of which there may otherwise be sufficient proof, the question of responsibility cannot present any serious difficulty. It may admit of doubt whether a person is responsible for not controlling his actions, or for not knowing right from wrong, or even in some cases for the harbouring of a delusion. But once let it be proved that an act is the natural result of a disease under which a person is known to labour, and the question must be practically removed from the field of discussion. Before, however, the principle can be accepted as fully satisfactory, it is necessary to inquire whether its application would permit insane persons to be held responsible who ought not to be so considered. In other words, are there states of insanity in which a person is irresponsible for acts to which he has not been predisposed or impelled by the insanity? It is perhaps impossible to give such an answer to this question as would be both definite and complete; but for practical purposes we think it may be answered in the negative. Where the insanity is of such a nature that it does not modify the whole conduct, we believe it will be found in practice necessary to admit the existence of responsibility for acts where there is no demonstrable connexion between them and the mental disease. The insane persons who on this principle might be held responsible, would be found solely among those whose irresponsibility could only be admitted after very searching inquiry, and whose insanity was of that kind and degree which has often been declared by medical writers to be consistent with responsibility. It is not to be supposed that under this rule difficulties would cease. It would often be hard to show in cases of actual disease that there was good reason for believing in its existence, or that it was really contributory to the act committed. This, however, would not result from any defect in the principle, but from that imperfection of our knowledge which renders the perfect application of any principle impossible. Let the task of the medical witness be limited to the demonstration of facts indicative of disease and its consequences, and he will at least be acting quite within his special province, and might expect that reasonable weight would be attached to his opinion. And if juries were instructed that the law does not hold a person responsible for acts committed under the influence of disease, it is scarcely conceivable that any one would be found guilty where good cause

had been shown even for the reasonable supposition of such an influence. Whatever may be the view ultimately adopted, it would seem to be in every way desirable that the attention of the medical expert should be confined to the elucidation of the medical facts, and that he should not be required to deal with questions which are legal and abstract, and in no way specially medical. The condition known as *diminished responsibility* has not been alluded to in this article. It is only indirectly recognised by British law, and therefore, though much is to be said in favour of its recognition, it is unnecessary to deal with the subject here. JOHN SIBBALD.

**CRISIS** (*κρίσις*, a decision, a turn).—SYNON.: Fr. *Crise*; Ger. *Krise*.—Crisis is a term applied to the rapid defervescence of an acute febrile disease. It has wandered somewhat from its original meaning, which was 'judgment'—primarily an operation in the mind of the observer, but reflected upon the phenomena observed. The converse term, employed to designate a gradual subsidence of fever, is *lysis*.

Crisis formed at one time the basis of an important medical doctrine. Certain days from the onset of the disease on which the crisis commonly occurred were considered to be propitious. The seventh day was especially favourable, while the sixth was the most unfavourable; speaking generally, the odd numbers or the multiples of 7 were propitious, and the even numbers and such odd numbers as stood near multiples of 7, such as 19, were unpropitious. The preparation also for a crisis was indicated, and the critical day foretold, by remissions perceptible some days previously. The whole morbid process of fever was represented as a process of elaboration by which a *materies morbi* was prepared for expulsion, and an essential feature of the crisis was a critical evacuation, by means of which this was eliminated.

The doctrine of crisis and even of critical days was not pure imagination or superstition, but was founded originally on careful observation. In times when nothing was known of the organic lesions which give rise to fever, and in countries where a large proportion of the diseases were of a malarious origin, it would afford data for prognosis and conduce to appropriate treatment; and at the present day in hot climates a crisis is anxiously looked for in febrile attacks on a given day, and, as is well known, a critical fall of temperature and improvement in the general symptoms precede in pneumonia improvement in the physical signs.

In order to constitute a true crisis the defervescence should occupy less than forty-eight hours, and it often takes place in a much shorter time. The fall of temperature should be accompanied by a corresponding reduction in the frequency of the pulse, and

should coincide with a feeling of relief and a return of strength; the skin will be warm and soft, the tongue moist, and there will be indications of reviving appetite; there may or may not be a critical evacuation, but the secretions will become more natural in amount and character.

This favourable mode of termination of an acute febrile disease is more common than is usually supposed. The circumstances under which it is most likely to occur are when the attack begins abruptly and the temperature rises rapidly, the natural course of the disease being short and not attended with organic lesions, such as will of themselves keep up fever. After twenty-one days, termination by crisis is not to be expected. The more marked the onset—as, for example, by a definite rigor—the more rapid the rise of temperature, and the greater the height to which it reaches, the greater the probability of an early critical termination.

**OCCURRENCE.**—The diseases in which the conditions favouring a crisis are realised, and in which this mode of termination is observed, belong to various classes.

Among the *specific fevers*, eruptive and continued, it occurs frequently in variola, but in severe cases it is interfered with by the febrile disturbance excited by the eruption. In measles it is very common. In scarlet-fever a true crisis is seen only in mild cases, though the onset of this disease is peculiarly abrupt. The mode of termination of typhus is essentially critical, but as a rule the crisis is not sharp. Relapsing fever affords the best examples of crisis, which is moreover attended by a critical evacuation in the form of profuse perspiration, the temperature sometimes falling 10° F. in as many hours, and the patient passing from a state of extreme suffering and oppression to almost perfect ease and comfort. In enteric fever *lysis* is the mode of termination.

Remittent fevers often present crises, which may be true and curative, or false and illusive; and the sun fever and common continued fever of hot climates, and tropical diseases generally, have a tendency to fever running high very early and breaking abruptly at a critical period.

In this country *feverish colds*, attacking the throat or taking the form of influenza or catarrh, often terminate critically in three or four days. Erysipelas may so end, but at a later and less definite period. The sharp *febrile attacks* which sometimes occur *after childbirth* often exhibit a very decided crisis. In *pneumonia* the natural termination is by a well-marked crisis, which may take place as early as the fifth day, or be deferred to the ninth, after which a critical termination is not to be expected, and the suspicion may be entertained that the case is not one of frank pneumonia, the prognosis becoming grave. As has been already stated, the general im-

provement precedes the indication by physical signs of resolution in the inflamed lung. Pleurisy is said also to terminate critically, but it is not in the same definite way as pneumonia.

The *critical evacuations* which entered into the original notion of a crisis are really a common attendant. The most common is a profuse warm perspiration, which may occur whatever the disease may be. Occasionally the evacuation is a copious flow of urine, or it may take the form of diarrhoea. Epistaxis or hæmorrhoidal flux is a more rare and doubtful critical evacuation. A common critical phenomenon is a prolonged, sound, and refreshing sleep.

The question whether or not a favourable crisis affects the odd rather than the even days has been a frequent subject of dispute, and it still remains undecided. It is not, however, of any importance; but another point handed down with the doctrine is worthy of attention, namely, that indications of an approaching crisis are often given two or three days beforehand in slight remissions of fever. By the presence or absence of such remissions at a certain period of the attack, or by a continuous rise of temperature where a remission might be expected, important prognostic information may be afforded and indications for treatment obtained.

**THERAPEUTIC INDICATIONS.**—The main therapeutic deduction from a study of crisis as a termination of acute disease is, that we should not hastily interfere with the reactions by which the system adjusts itself to altered conditions or meets the incidence of the causes of such disease, but contribute to their completion. We do not assume the existence of a *vis medicatrix* tending invariably to the restoration of health; but we must recognise the power inherent in a living organism to respond by internal changes to external influences, and to regain the balance when this has been disturbed. In this process a certain cycle of changes must be gone through, and the great opportunity for treatment of an active kind, should any be required, arises when the course, direction, and probable duration of these changes are known, and when agencies can be brought to bear at a given moment, which will contribute to bring about the appropriate critical evacuation or a critical sleep, through which a return to a normal condition would naturally be effected. WILLIAM H. BROADBENT.

**CRITICAL.**—Having relation to a crisis. See CRISIS.

**CROUP** (Scotch, *croup* or *roup*, hoarseness).—SYNON.: *Cyananche trachealis*; Fr. *Croup*; Ger. *Croup*.

**DEFINITION.**—An acute febrile affection, occurring in childhood, accompanied by inflammatory swelling of the mucous mem-

brane of the larynx, and in some rare cases by the formation of a fibrinous false membrane.

**ÆTIOLOGY AND PATHOLOGY.**—The symptoms of the most usual form of croup, as described below, are due to an acute catarrh of the laryngeal mucous membrane. The condition is, in fact, a simple catarrhal laryngitis, and is not accompanied by the formation of any false membrane. The mucous membrane swells by reason of the congestion of its blood-vessels, and the pouring out of inflammatory exudation into its tissue. Mucus, too, is prone to accumulate on its surface. These conditions are precisely the same as occur in the ordinary catarrhal laryngitis of adults. But in the child the glottis is much narrower than in adults, and the swelling of the mucous membrane from inflammation is greater, and more rapid in reaching its height. Moreover, the larynx is in children more irritable, and therefore its muscles are more easily excited to spasm. Thus when a simple catarrhal laryngitis makes its appearance in a child, it is very shortly followed by laryngeal stenosis, partly from the swelling of the mucous membrane, partly from accumulation of mucus, and partly too from spasm of the laryngeal intrinsic muscles. The condition described is most often due to exposure to cold and damp, especially at a time when the body is heated. It is caused also by scalds of the larynx, when unduly hot fluids are drunk by accident, by wounds, by the irritation of noxious gases, and by the presence of foreign bodies in the larynx. It is more common in male than in female children, and is usually met with between the ages of two and nine years.

But there also exists an inflammation of the larynx which is accompanied by the formation of a false membrane, and it is in respect to this condition that so much discussion has arisen, and even now doubt exists in the minds of some observers. It is, of course, well known that in diphtheria the characteristic membrane may spread from the pharynx, its usual site, into the larynx, and in doing so may produce all the symptoms of so-called croup, in addition to those due to the diphtheria proper. But much of the confusion which existed as to the pathological entity of croup resulted from the non-recognition of those cases of diphtheria in which the local lesion had its primary seat in the larynx. Pathological observations, however, have now placed it beyond doubt, that such cases really exist. Death may occur entirely from the laryngeal stenosis so produced, as in all other and simple obstructions of the larynx. But the diphtheritic nature of the affection is obvious from the other possible terminations of such cases, and from the general symptoms present at the height of the affection. Thus death may also be due to the heart-failure,

or to the general blood-poisoning, characteristic of diphtheria. Again, in the acute stages of such a disorder, symptoms may appear, such as great asthenia, excessively frequent pulse, hæmorrhages from various parts, albuminuria, and a formation of diphtheritic membrane on sores far removed from the larynx, which symptoms, while inconsistent with a diagnosis of non-specific membranous inflammation of the larynx, are frequent associations of diphtheria when it occurs in its ordinary form. Moreover, when, in fortunate cases, the acute symptoms have passed away, after an interval the characteristic paralysis of diphtheria may show themselves. The facts of contagion are also of importance, for from such cases of membranous laryngitis, other cases may arise, in which the diphtheritic membrane appears first in the pharynx, and the disease runs its ordinary and unmistakable course. The teachings of bacteriology are perhaps, as yet, not sufficiently definite, in reference to this point, for them to be accepted as absolute proof. It may, however, be noticed that Löffler's diphtheria-bacillus (not merely the micrococci which may be found in any decaying membrane) has been demonstrated equally well in those cases of diphtheria which presumably began in the larynx, as in those where the membrane was limited to the pharynx. Thus it must now be admitted that the local lesions of diphtheria may be limited to the larynx; and, in the opinion of the writer, under this category must be placed by much the larger number of cases formerly styled 'membranous croup.' The description of diphtheria of the larynx will be found in the article **DIPHTHERIA**.

There remains still a certain proportion of cases of membranous laryngitis which are not due to the action of the diphtheritic poison. Some of these are produced as secondary complications by the poisons of other specific fevers, and amongst these are to be mentioned scarlet-fever, small-pox, measles, enteric fever, and whooping-cough. Yet this question is before us, whether a membranous laryngitis may occur without the action of any specific poison. The older writers assumed that this occurred in a large number of instances, and the prevalence of this view led to the report by a Committee of the Royal Medical and Chirurgical Society in 1879, upon the Relations of Membranous Croup to Diphtheria. That by far the larger number of cases of membranous laryngitis are, in the opinion of the writer, due to diphtheria has already been stated above. But the evidence is also indisputable that the affection may occasionally arise from other and simple sources. Thus, the late Dr. Hilton Fagge<sup>1</sup> recorded, amongst others, cases where both the fauces and air-passages were covered with false membrane, from a

<sup>1</sup> Guy's Hospital Reports, 1877, p. 345.

scald of the throat by boiling water, and again from burns of the fauces; where a foreign body in the bronchus had caused membranous laryngitis; where a similar appearance followed a cut throat, other diseases of the pharynx or larynx not diphtheritic, and pneumonia.

Mr. R. W. Parker,<sup>1</sup> too, has recorded a case where false membranes formed in the larynx after a scald. The Committee mentioned above, reported that cases had fallen under their notice, where 'membranous affection of the larynx and trachea had shortly followed exposure to cold, but their knowledge of the individual cases was not sufficient to exclude the possible intervention or co-existence of other causes.' General pathology would not negative the view that an inflammation, usually simple, might occasionally become membranous. As is mentioned under DIPHTHERIA in respect to the true diphtheritic membrane, an important factor in its production is the occurrence of coagulative necrosis of the epithelial cells, a condition which may arise from the intense action of an irritant usually productive only of catarrhal inflammation. We have a formation of false membrane, analogous to that of the assumed membranous and non-diphtheritic croup in the affection known as plastic bronchitis, in the intestine in dysentery, in the mouth in syphilitic and sometimes in simple stomatitis, and on various mucous surfaces in septic disorders. Further, membranous inflammation has actually been produced experimentally by the injection of acrid irritants into the larynx of animals. *A priori*, therefore, there seems no reason why a membranous laryngitis should not occur without the intervention of a specific poison. Practically, however, it must be concluded, from the evidence at our disposal, that such cases are exceedingly rare, and that false membranes do not form in the laryngitis which forms the basis of what is met with as the simple non-diphtheritic croup of children. It must here be stated, that in modern times the late Dr. Hilton Fagge held an opposite view, though he with great care and fairness considered the arguments against the position he maintained. He believed not only that, in many cases of croup which recovered, false membrane had formed without being detected, but also that a non-specific membranous croup might spread from the larynx to the pharynx and fauces, causing fresh deposits of false membrane on those parts, which most other observers would assume to be characteristic of diphtheria. He suggested that the term 'Croup' should be applied only to cases of membranous and non-diphtheritic laryngitis, while those where no membrane was formed should be known as 'Spurious Croup.'

In former accounts of the pathology of

<sup>1</sup> Clinical Transactions, 1875, p. 144.

croup, differences are described between the croupal and the diphtheritic false membranes. There are, indeed, differences between the false membranes found on the laryngeal and pharyngeal mucous membranes respectively; but these are due merely to the differences in structure of the mucous membrane attacked. The false membrane is in both cases essentially the same in structure and in its mode of formation. What is said of the diphtheritic membrane will apply to the membrane rarely found in croup, so that no detailed description of the latter need be given here. See DIPHTHERIA.

SYMPTOMS.—In accordance with the view expressed above, little will be said under this heading about cases other than those of non-membranous, or as the late Dr. Hilton Fagge styled it, 'spurious' croup. The child affected by this disorder may suffer from general catarrhal symptoms for a time, varying from a few hours to two or three days. More commonly before the actual attack he appears quite well at bed-time, though very often it may afterwards be ascertained that some time during the day he has been exposed to cold or damp, or has sustained a chill. In a few hours, however, he wakes suddenly, as if frightened, breathing hurriedly with loud, hoarse, inspiratory laryngeal stertor. He coughs frequently, making a harsh, metallic noise, but at first removing no mucus from the larynx. He cries, and perhaps speaks, in a shrill, cracked tone, which soon gives place to a mere whistling sound. The character of the breathing, voice, and cough gave rise to the Scotch vernacular name for the disease, 'croup,' which was adopted by Dr. Home in 1765, when describing the affection, and which is now employed by most nations as a scientific term. The child is very restless, tosses his body and limbs about incessantly, clutches at his throat as if to remove the obstruction there, and seizes any surrounding objects with his hands. The face is at first flushed, the eyes bright, and the expression exceedingly alarmed and anxious. Soon, however, the flush becomes dusky, and gradually pallor supervenes, while the whole body is covered with a cold sweat. The feet, and sometimes the hands, not infrequently assume the position found in tetany, and in extreme cases general convulsions may occur. The pulse is frequent and feeble, the temperature is slightly raised. The difficulty with which air enters the chest is obvious from an observation of the patient's position and respiratory movements. The head is thrown backwards, the chin held out prominently, and this position is accentuated at each inspiration by a contraction of the sterno-mastoid muscles. All the extraordinary muscles concerned in chest-expansion are brought into play, and the nostrils dilate at each breath. Yet, in spite of the extra force employed, the thorax is not filled with

air. During inspiration the supra-clavicular fossæ, the lower ribs, the epigastrium, and even the lower portion of the sternum are depressed. The yielding of the chest-wall is, as might be expected, more pronounced in rickety children, and in such subjects the whole of the ribs may be seen to give way at the sides as each breath is drawn. If the chest and larynx be auscultated, at first nothing is heard but laryngeal sibilus; afterwards rattling noises are perceived in the larynx, due to the presence of mucus, while in the chest rhonchi may be discovered. The cough, which was at first dry, as the attack continues displaces small pellets of thick, tough mucus; sometimes threads of this substance are expectorated, and have been mistaken for false membrane.

Usually, after a time varying from half an hour to two or three hours, the difficulty in respiration subsides, and the child falls asleep again, but not quite free from symptoms indicative of his ailment. His face is somewhat flushed, and there is some degree of pyrexia. The restlessness does not quite disappear even in sleep. The hands and feet frequently retain their tetanoid position. The breathing is still husky and somewhat hurried, and an occasional slight cough has the clanging character noticed during the paroxysm; during the next day, or for the next two or three days, the breathing is hurried and somewhat stertorous, and the attack may return during the next and even succeeding nights. For some time after recovery is apparently complete, any slight cough is prone to assume a 'croupy' character, just as after an attack of whooping-cough the characteristic whoop may at times recur. After one attack, too, or series of attacks, the child may again and again suffer from repetitions of the disorder, even for several years.

As has been stated, this non-diphtheritic membranous laryngitis is not always idiopathic. In such cases the signs of laryngeal stenosis are added to those of the original disease or injury. It is convenient, therefore, to discuss them in the article on DIPHTHERIA, where they will be found in the section upon Diphtheria of the Larynx.

PROGNOSIS.—The prognosis of non-membranous croup is almost invariably favourable in so far as the actual attack is concerned. In spite of the apparent severity of the symptoms, they nearly always subside naturally. The friends of the patient should, however, be warned of the probability that the attack will be repeated at times for some years after its first appearance. Membranous croup, on the other hand, is a much more serious matter. At any moment the false membranes may accumulate or curl up in the larynx, and entirely close the glottis. Nor is the danger merely that of the laryngeal affection. The laryngitis occurs in only severe cases of the specific fevers, and the

blood-poisoning of the original disorder, just as in diphtheria, is usually a most fatal condition.

TREATMENT.—As soon as the attack of non-membranous croup has commenced, the child should be placed in a warm bath, to which preferably a little mustard has been added. Sponges, wrung out of water as hot as can be borne, should be applied over the larynx, and renewed as often as they become cold; or a mustard-leaf may be applied here. An emetic, too, is useful. This may be administered in the form of ipecacuanha wine, in doses of one teaspoonful every ten minutes until vomiting comes on. Sir William Jenner recommends that afterwards a dose of calomel and jalap should be given. It is well, too, to place the child in a tent-bed, under the cover of which the nozzle of a steam-kettle is introduced.

Prophylactic treatment is of importance, when the disease has once shown itself. In cold weather the child should be wrapped up warmly, and protected from chills and draughts. At the same time, the larynx may be, as it were, accustomed to cold, by being sponged once or twice a day with cold water. General tonics, too, are of use in warding off future attacks.

The treatment of membranous croup is practically the same as that of laryngeal diphtheria. See DIPHTHERIA.

ROBERT MAGUIRE.

**CROUP, FALSE.**—A term commonly applied to laryngismus stridulus. See LARYNX, Diseases of.

**CROUPOUS, CROUPY** (Scotch, *croup*, hoarseness).—These terms were originally employed with reference to the peculiar crowing or stridulous character of the respiration, cough, and voice in certain affections of the larynx, and signified 'belonging to croup' in its clinical relations; for example, 'croupy cough,' 'croupy symptoms.' When morbid anatomy demonstrated the occurrence of a fibrinous exudation or false membrane upon the affected surface in a special form of croup, the word 'croupous' was used also to designate this false membrane; thus 'croupous exudation' and 'croupous membranes.' The application of the term was afterwards further extended; and it is now employed to indicate the process that leads to a fibrinous exudation in any situation whatever; such as 'croupous inflammation' and 'croupous pneumonia.' Thus the words 'croupous' and 'croupy,' which were originally associated with peculiar sounds, have come in a remarkable manner to express certain physical, chemical, and microscopical characters in the products of inflammation. See CROUP; DIPHTHERIA; and INFLAMMATION.

**CROWING CONVULSION.** — A popular synonym for laryngismus stridulus. See LARYNX, Diseases of.

**CRURA CEREBRI, Lesions of.**—In the crura cerebri lie the paths of communication between the cerebral hemispheres and the periphery. The motor or pyramidal tracts lie in the *foot* or ventral portion of the crus, which is separated from the dorsal portion, or *tegumentum*, by the *locus niger*. The pyramidal tracts of the internal capsule constitute only the middle third of the foot of the crus; the inner third connects the prefrontal lobe with the grey matter of the pons, and, indirectly perhaps, with the opposite cerebellar hemisphere (Flechsig); the outer third, which has been supposed by Meynert to constitute the sensory path, would appear, from the researches of Flechsig and others, to connect the occipito-temporal regions of the hemisphere with the grey matter of the pons, and probably with the cerebellum. The sensory tracts, in all probability, run in the tegumentum or dorsal division of the crus cerebri. The fibres of the third nerve pass through the internal, or mesial, aspect of the crus on their way to the oculo-motor nuclei in the floor of the aqueduct of Sylvius.

From the anatomical and functional relations of the crus cerebri, lesions of this region, such as may arise from hæmorrhage, pressure, &c., are apt to cause paralysis of motion and sensation on the opposite side of the body, as well as oculo-motor paralysis on the same side as the lesion. The degree of implication of the sensory and motor tracts and fibres of the third nerve varies in individual instances; but an *alternate paralysis*, in which there is some degree of oculo-motor paralysis on the one side and paralysis of the limbs on the other, is diagnostic of lesion of the crus. A typical instance of this form of paralysis has been recorded by Weber (*Med.-Chir. Trans.* 1863). In this case there was oculo-motor paralysis on the side of lesion and complete paralysis of voluntary motion, with partial paralysis of sensation on the opposite side of the body. A similar case has been recorded by Rosenthal (*Med. Jahrb.*, 1870). In this case there was, progressively, ptosis on the left side, right hemiplegia, anæsthesia and analgesia. The right third nerve became implicated later. After death a cyst was found in the left crus cerebri, together with a tumour of the size of a bean occupying the interpeduncular space, and compressing the right third nerve. In paralysis from lesion of the crus cerebri, there is, as a rule, also well-marked vaso-motor paralysis, and the temperature of the paralysed side may be two or three degrees above that of the other.

D. FERRIER.

**CRUSTA LACTEA** (*crusta*, a crust; and *lactea*, milk-like).—Milk-crust: a synonym for *eczema pustulosum* of the face and head, met with in infants at the breast. See ECZEMA.

**CRUVEILHIER'S PARALYSIS.**—

A synonym for progressive muscular atrophy. See PROGRESSIVE MUSCULAR ATROPHY.

**CUPPING.**—SYNON.: Fr. *Action de ventouser*; Ger. *Schröpfen*.

This is a mode of treatment sometimes employed to relieve congestion or inflammation of internal parts by drawing blood to the surface of the body. When the blood thus attracted to the superficial parts is actually abstracted from the body by means of incisions, the operation is called *wet-cupping*; and this has been described in the article BLOOD, Abstraction of. We shall here describe *dry-cupping*, in which no scarifications are made, the blood being simply drawn towards the surface by atmospheric exhaustion, and hyperæmia of the subcutaneous parts or organs thereby relieved.

Formerly cupping was extensively practised, but of late years it has fallen into disuse. In some respects it serves the purpose of counter-irritants, but has a more powerful effect than these; rapid and marked results being sometimes produced upon the circulation of inflamed or congested tissues.

**MODES OF APPLICATION.**—Dry cupping is performed as follows: The flame of a spirit-lamp, being allowed to burn for an instant in the dome of a cupping-glass, is quickly withdrawn, and the cup is then rapidly and evenly applied to the skin over the affected part. The heat expands the air contained in the glass cupola, and, owing to the contraction which ensues on cooling, the skin is forcibly sucked up into the cup. It is well first to sponge the skin of the selected spot with hot water, so as to render it more supple and vascular. Slightly moistening the rim of the cupping-glass helps to increase the degree of exhaustion.

An excellent modification of cupping, which has been demonstrated to the writer by Sir Richard Quain, is practised in the following way: Instead of allowing the cup to remain stationary after its application to the skin, as is usual, the operator dexterously slides it to and fro along the surface. When the operation is to be thus performed the amount of surface drawn into the glass must not be considerable. In this way a large tract of skin may be quickly rendered hyperæmic without effusion of blood into its meshes, as happens when the cups are stationary.

**PRECAUTIONS.**—Cupping-glasses should be applied where the skin is thick and cushiony, as over the loins, nape of the neck, pectoral region of the chest, &c., and not where bony prominences, or other irregularities, are likely to interfere with complete exhaustion. The edges of the glasses must not be so hot as to burn the skin.

**USES.**—Cupping may be advantageously employed in cases of sthenic cerebral congestion, the cups being applied to the nape of the

neck; in hyperæmia of the spinal cord; and in inflammation or congestion of the lungs, kidneys, or other viscera. In renal ischæmia it is eminently serviceable. This may be owing to the fact that the blood-supply of the skin of the loins is in intimate relation with that of the kidneys; the vascular supply to those organs being thus directly and immediately influenced. ALFRED WILTSHIRE.

**CUTIS, Diseases of.**—See SKIN, Diseases of.

**CUTIS ANSERINA** (*cutis*, the skin; and *anser*, a goose).—A state of roughness of the skin, resembling that of a goose when plucked, produced by prominence of the pores or follicles. It is due to contraction of the muscular structure of the corium, and is commonly occasioned by cold.

**CYANIDES, Poisoning by.**—See ANTIDOTE; and PRUSSIC ACID, Poisoning by.

**CYANOSIS** (*κυανός*, blue).—This, which is really not a disease, is the peculiar blue or more or less livid colour of the surface of the body, especially in certain parts, which is observed in several affections that interfere with the circulation and oxygenation of the blood. The condition is most commonly associated with certain forms of congenital malformation of the heart, and reaches its highest development in them, for which consequently cyanosis is not uncommonly used as a synonym. Lesser degrees of similar discoloration are, however, not infrequently noticed in cases of cardiac disease developed after birth, and they may also accompany pulmonary affections which materially obstruct the circulation. A cyanotic appearance is also one of the obvious effects resulting from all modes of suffocation, and it is observed in the collapse-stage of cholera. The upper half of the body may become extremely cyanotic as the result of obstruction of the superior vena cava. For the pathology of cyanosis, see HEART, Malformations of.

**CYNANCHE** (*κύων*, a dog; and *ἄγχω*, I strangle).—SYNON.: Fr. *Angine*; Ger. *Bräune*.

This word is used to express an inflammatory condition of the throat, or contiguous parts, in which difficulty of breathing or of swallowing exists, accompanied by a sense or feeling of choking. The term is used synonymously, more frequently on the Continent than in England, with *angina*; an affix, indicative of the seat or nature of the affection, being employed as a designation for each of the several forms or varieties of disease affecting the throat or adjacent parts. Such, for example, are the terms *cynanche laryngea*, or croup; *cynanche maligna*, or malignant sore-throat; *cynanche parotideæ*, or mumps; *cynanche pharyngea*, or inflammation of the pharynx; and *cynanche tonsillaræ*, or quinsy. See these several diseases.

**CYRTOMETER** (*κυρτός*, curved; and *μέτρον*, a measure).—An instrument for measuring the absolute and relative dimensions and movements of the chest-wall. See PHYSICAL EXAMINATION.

**CYSTICERCUS.**—See ENTOZOA.

**CYSTINE** or **CYSTIC OXIDE** (*κύστις*, the bladder).—A peculiar substance, occurring either in solution or in the form of small crystals in the urine, or as calculi in connexion with the urinary apparatus. See URINE, Morbid Conditions of; and CALCULI.

**CYSTITIS** (*κύστις*, the bladder).—Inflammation of the bladder. See BLADDER, Diseases of.

**CYSTOSCOPE** (*κύστις*, the bladder; and *σκοπέω*, I inspect).

**DEFINITION.**—An instrument designed for inspecting the interior surface of the urinary bladder.

**INTRODUCTION.**—Progress in the improvement of the means for inspecting the interior of hollow organs was slow from the beginnings of Bozzini (1807), Segalas (1826), Avery (1846), and Desormeaux (1853 and 1865), and of others by whose apparatus light outside the body was thrown through an inspecting tube on to the surface of the bladder. Among the many workers in endoscopy, Avery and Grünfeld (1874) were conspicuous for their originality and fertility of resource. Avery devised the means of reflecting light in sufficient amount to illuminate the urethra, and his apparatus was modified by Desormeaux and others, but greatly improved by Grünfeld. That surgeon described many conditions of the interior of the bladder in health and disease when seen during life. Dittel and Nitze, in 1876–1879, fixed an electric glow-lamp to the beak of an instrument, and thus carried the source of light into the bladder itself, and so obtained a great intensity of illumination. Nitze, by suitable optical contrivances, brought into view nearly all the surface of the bladder. Previously, when light reflected from without was employed by Grünfeld and others, only a small part of the wall of the bladder—that in immediate contact with the tube—could be seen.

Nitze has arranged the lamp differently in a second instrument, to obtain a view of that small portion of the bladder which the ordinary cystoscope may miss.

**APPARATUS.**—Leiter's forms of Nitze's instrument are the most useful for internal inspection. The apparatus is contained in two tubes, one of which slides in the other. The outer one has the form of an ordinary *coudé* catheter, the angle of junction of the beak with the stem being 130 degrees. The electric

current for supplying the lamp passes in through the tube itself, and back by an insulated wire carried in a groove inside the outer tube. The stem just above the angle of the bend is cut away at one side where a right-angled prism is cemented into it. This prism has its hypotenuse silvered, so that rays passing through the exposed face of the prism may be reflected into the inner tube. The inner tube is straight, about eight inches long, and slides in the outer tube. It carries four lenses: one, at the end farthest from the observer, is a hemispherical lens, the flat face of which, on pushing the tube in, goes quite close to that face of the prism which is at right angles to the axis of the instrument. Near to this hemispherical lens is another of very short focal length. The two lenses, receiving rays reflected at the hypotenuse of the prism, form a small image of objects situated opposite the prism, within a field of, say, 45 degrees diameter. This image is very near to the inner surface of the second lens. At the middle of the inner tube is a third lens of focal length somewhat less than one fourth of the length of the tube. This lens takes up the little image from the first and second lenses, and forms of it another image of nearly the same size not far from the end of the tube near the eye of the observer. Lastly, there is a short-focussed lens at the eyepiece for viewing the image formed by the third lens. For convenience we may call this inner tube and four lenses "the telescope."

Besides the telescope and the insulated wire, recent instruments contain two small tubes—one for conveying an inflowing stream of some sterilised or antiseptic fluid to distend the bladder, and keep its contents clear during inspection; the other for allowing the injected fluid to escape after circulating in the bladder, carrying with it any blood or muco-pus not evacuated before the cystoscope was introduced. By a Higginson's air-pump, acting on a reservoir, the stream is maintained constantly, and the bladder-walls are firmly distended—a very important condition for satisfactory inspection. This modification for irrigating during inspection was brought into notice by the present writer.

With the cystoscope above described the observer, on looking down the telescope, obtains a view of that portion of the illuminated surface which is situated within about 25 degrees of a perpendicular to the exposed face of the prism, provided the bladder be fairly distended with fluid. The whole surface of the bladder may be examined, in most cases, by pushing the prism farther into the bladder, or by drawing it back, or by turning the instrument on the axis of the stem, or by tilting the stem. But it is obvious that the parts of the surface near where the instrument enters, and in the region opposite to it, are difficult to bring into view in a satisfactory manner.

Nitze has accordingly some different forms of cystoscope adapted specially for those cases, the principal one of which has the window placed in the beak opposite the outer side of the bend, and the light at the farther or posterior end of the beak. By this arrangement the light is thrown directly upon the floor of the bladder, and so passes through the window to the telescope. This form of cystoscope illuminates the area between the uvula and the mouths of the ureters, and often reveals changes there not detected with the ordinary form.

In interpreting the significance of the images obtained, account must be taken of the varying distance and obliquity of different parts of the surface. This will evidently be a matter of difficulty, to be overcome by practice, especially by practice on a model of the bladder, in which the various natural landmarks are represented in bold exaggerated figures.

**APPLICATION.**—In the use of the cystoscope little can be seen if the cavity be not distended or if the contents of the bladder be turbid. When about six or eight ounces of fluid are injected, the surface of the bladder is fairly smooth, reddish or yellow, and racemose blood-vessels collecting into trunks towards the base of the viscus are very distinct. If the walls be tightly expanded the surface may seem glistening white, like mother-of-pearl. On the floor, the trigone is dull red, granular, and somewhat prominent. Near the ends of the ridge at the base of the trigone are placed in two little eminences the openings of the ureters. If the urine coming from a kidney be turbid with pus or other matter, a jet of this turbid fluid can often be seen issuing from the eminence and so discovering the orifice of the ureter. Similarly, if there be ulcers on the mucous membrane, or a papillomatous tumour, a jet of blood can be seen occasionally to dart through the clear fluid, which speedily renders it a luminous red fog, through which nothing definite can be described. In such cases the apparatus for maintaining a constant flow of ice-cold boracic solution through the bladder is of great service, as the opaque fluid is displaced through the outlet tube, and transparency is restored; and an artificially chilled solution represses hæmorrhage during inspection. If the contents of the bladder be allowed to escape during examination, the view becomes dark, or so indistinct as to prevent recognition of any known object, and then there is danger of the lamp growing hot and injuring the wall of the bladder in contact with it. Hence, whenever the view ceases to be luminous, the electric current should be at once cut off and the bladder refilled. The various changes effected in the appearance of the bladder by disease are described in the article **BLADDER, Diseases of**.  
BERKELEY HILL.

**CYSTS.—DEFINITION.**—The word 'cyst' (*κύστις*, the urinary bladder) is used in pathology without strict scientific accuracy for a closed cavity containing fluid or soft matter; which cavity will have, from the nature of its contents, a spherical or spheroidal shape. The objects thus defined differ much among themselves, and are associated together rather from convenience than on account of any real pathological similarity.

**CLASSIFICATION.**—Cysts may be classified according to their structure, as simple or compound; according to their contents, as serous, mucous, fatty, &c.; or according to their mode of origin. The latter, though not free from objection, is the basis of description which will be here adopted. Cysts may originate: (1) from *dilatation* of previously existing closed cavities; (2) from *retention* of the products of secretion of a secreting gland; (3) as a part of *new-growth*; (4) by a vice of *development*. These kinds are distinct structures with a wall lined by epithelium. But the name is often given, less accurately, to spaces containing fluid which result from softening of solid tissue, whether in a new-growth or in an inflammatory product. Cystic parasites have also been confounded with cysts properly so called.

1. **Cysts from Dilatation.**—Spaces, normal or newly formed, in connective tissue may, by irritation and consequent excessive exudation, be converted into cysts; or the same result may happen from the confluence of several such spaces. In proportion as the wall becomes smooth, and the shape uniform, they may be called cysts. Bursæ, whether normal or pathological, are cysts. Ganglion in the sheath of tendon is clearly a pathological cyst. To these and like structures the name *hygroma cysticum* has been given. They all contain clear serous fluid, and are lined by an endothelium. Encysted hydrocele may also be called a cyst. One class of ovarian cysts comes under this head, those, namely, which are due to simple dropsy of the Graafian vesicle. Tubo-ovarian dropsy has the same explanation; and cysts of the broad ligament are enlargements of normal structures which are left as relics of the development of the ovary. The thyroid gland seems, from its structure, containing as it does so many closed follicles, particularly disposed to this kind of cyst-formation, and this is doubtless the explanation of bronchocele. The cause of such an enlargement of closed follicles is very obscure, but appears to be immediately due to increased production of the material normally filling the space.

2. **Cysts from Retention.**—Cystic formations may result from the obstruction of the natural outlet of a secreting organ, and the consequent retention of secretion. It is necessary that the walls of the secreting cavity should admit of enlargement, and that

the tension should not become so great as to check secretion.

All secreting glands present instances of such cysts. The sebaceous glands of the skin are particularly liable to obstruction of their ducts, and in this way are formed sebaceous cysts, the contents of which are sometimes epithelium and the products of normal secretion, sometimes abnormal products. The same term has, with less propriety, been applied to the sebaceous productions called milium and comedo. See FOLLICLES, Diseases of.

The glands or mucous surfaces are liable to similar obstructions, and *mucous cysts* result, such as are sometimes seen in the mouth. Larger cysts in the mouth (*ranula*) result from the obstruction of the ducts of the salivary glands, or are perhaps connected with an abnormal production of gland-substance. The stomach very frequently, other parts of the intestinal canal more rarely, show similar cysts, which, when they project and become complicated in structure, are called polypi. They are occasionally seen on the larynx and trachea. In no part are mucous cysts more frequent than in the uterus, where, indeed, similar formations, the *ovula Nabothi*, must be regarded as normal. The varieties here met with have, as Virchow has pointed out, a close analogy with the various forms of retention-cysts in the skin.

In the mamma, cysts may result from the cutting off of portions of the gland-follicles, but the cysts contained in mammary tumours are not always formed in this way, some being part of new-growths. In the testicle obstruction and cutting off of seminiferous tubes may lead to small cysts, but these are more often connected with new-growths. The curious cysts known as *spermatocetes*, containing spermatozoa, appear to arise from a similar distension of detached portions of testicle-substance, which, by an error of development, have failed to become connected with the excretory ducts. The testicle is also liable to a general cystic degeneration, usually called *cysto-sarcoma*. Cysts of the kidney are of various kinds, but many, no doubt, both large and small, result from the dilatation of uriniferous tubules and capsules of glomeruli when their outlet is obstructed, as occurs in the cirrhotic form of Bright's disease. The origin of the very numerous microscopic cysts has been much disputed. The writer inclines to the belief that they arise from moniliform contraction of the uriniferous tubes, especially such as contain the hyaline cylinders, known as fibrinous casts. Another form of cystic disease of the kidney is developmental. In this the whole of the organ is converted into a mass of cysts, and is usually much enlarged. This condition may be congenital, and the organ may be so large as to obstruct parturition. It is

attributed by Virchow to inflammation of the calyces during intra-uterine life.

To guard against a common error of language, it should be pointed out that the condition of the kidney which results from the obstruction of the ureter, or of the urinary passages lower down, though sometimes called cystic dilatation of the kidney, is not properly a case of cyst-formation, and is better called *hydronephrosis*.

3. **Cysts from New-Growth.**—In many forms of new-growth cysts are produced, but not always in the same way. Occasionally, as in myxoma and enchondroma, softening of portions of new-growth already formed produces spaces containing fluid, which are sometimes, though hardly correctly, called cysts. In many sarcomata, the production of new tissue goes hand in hand with that of cysts, and is sometimes effected, as in glandular organs, by the formation of new follicular structures without an outlet, sometimes by new-growth into the dilated cavities. Polypoid or pedunculated growths on a free surface may sometimes, by the fusion of their extremities, enclose spaces which become converted into cysts. We do not often find cysts forming by themselves a new-growth of so definite a character as to deserve a separate name. When they do so, they may be called *cystoma*.

#### 4. **Cystoma or Cystic Tumour.**—

Cysts are met with in the ovary which come under the definition just given, namely, so-called *compound multilocular cysts*, which constitute the well-known formidable cystic disease of the ovary, and sometimes produce tumours of immense size. In these the originally simple primary cyst appears to become complicated by the formation in its walls of secondary cysts, which may encroach upon or project into the primary. Again there may be papillary growths starting from the inner wall of the primary cyst, which either fill it up, or by fusion enclose spaces, which become secondary cysts. Very complicated structures thus result. The contents may vary in consistence and colour, from clear, pale, albuminous liquid to gelatinous matter, and may be stained through hæmorrhage, or purulent through inflammation. The origin of these structures, which have no precise parallel in other parts of the body, is extremely obscure. It is not even certain whether the primary cysts commence, as might seem *primâ facie* highly probable, in the Graafian follicles; but they are plainly due to an error of development, possibly beginning in early intra-uterine life, and are not set up by any external causes. The presence of a tubular gland-tissue, such as is found in the rudimentary, but not in the perfect ovary, confirms this view, by throwing cyst-formation back into an early stage in the development of the organ.

In another, but rarer, form of cystic

disease of the ovary, equally due to an error of development, and sometimes congenital, the whole organ is found converted into a mass of small cysts, with no striking inequality of size. This variety resembles one form of cystic disease in the testicle and kidney.

*Dermoid cysts* are those of which the wall is composed of skin or mucous membrane, and generally lined by a layer of flat cells resembling epidermis. The wall may be complicated with connective tissue, forming papillæ resembling those of true skin, and may contain hairs, sebaceous glands—either in connexion with them or unattached—and sudoriparous glands. The accumulation of fatty matter within the cysts is doubtless the result of the continuous activity of the sebaceous glands, the products of which cannot escape. Large masses of hair may also be found, from continuous growth, and there are often numerous detached epidermic scales. Distinctly formed mammary glands, with nipples, are sometimes found. Such a cyst has only the characters of a portion of skin, which might be imagined inverted and included by the growth of the surrounding parts in an early stage of development—an explanation which applies only to those situated in certain parts of the integument where a junction has normally taken place—*e.g.* along the lines of the branchial fissures in the neck, in the anterior middle line of the body, &c.

These simple dermoid cysts are sometimes complicated by containing teeth, it may be in very large numbers (*dentigerous cysts*); but since teeth may also be regarded as cutaneous products, the cyst may still have originated in the skin. This explanation no longer holds, however, when masses of bone are found, sometimes serving for the attachment of teeth, sometimes separate; as well as other tissues, *e.g.* nervous tissue and striated muscle. Cysts with this variety of contents have been called *proliferative*. Dermoid, dentigerous, and proliferative cysts appear to be always congenital structures, but may show further growth and development in after-life. At least two-thirds of the known cases have occurred in the ovaries. Next to these organs, the testicles are the most frequent seat, but these cysts have been also found in other parts of the body-cavity, in the mediastinum, lung, and even within the skull. The origin of these growths is extremely obscure; but it is desirable to reject entirely the hypothesis that a mixed tumour of this kind can be the remains of an undeveloped fetus included in the perfect individual; a hypothesis rendered improbable by the extreme irregularity of the tissues produced, the teeth, for instance, sometimes numbering one hundred or more. It would rather appear as if, in some instances, a portion of embryonic epithelial tissue had

become misplaced at an early period of development. In other cases, these cysts originate in obsolete canals, representing rudimentary structures; such as the central canal of the nervous system, the post-anal gut, the branchial clefts, the vitello-intestinal duct, and others.<sup>1</sup>

Several parasitic animals infesting the human body may appear in an encysted form, and may resemble in appearance true pathological cysts. The commonest—the larval form of *Tænia echinococcus*, or *hydatid cyst*—is known by its laminated wall, and by containing a fluid which is not albuminous, but holds in solution sodium chloride. *Cysticercus cellulosa* has a transparent wall and clear contents. The other encysted parasites are either very small, as *Trichina spiralis*, or unimportant.

**CONTENTS OF CYSTS.**—The serous cysts and hygromata contain an albuminous fluid like that of serous cavities, which may hold

enough fibrinogenous material to coagulate spontaneously. Leucocytes may also be present. If inflammation be set up, the proportion of albumin and of leucocytes becomes greatly increased. In the fluid of mucous cysts mucin is contained; in that of colloid cysts, little-known substances which are allied to gelatin. Sebaceous cysts contain neutral fats—sometimes hard, sometimes fluid, and cholesterin. Both mucous and sebaceous products may harden into concretions, and even become calcareous. In renal cysts urea has been found; in biliary cysts, bile-pigment; and in general the products of special secretion may be found in cases of retention, at least in early stages; but if retention last too long, special secretion may cease. Various exceptional contents have been already enumerated.

**TREATMENT.**—The treatment of cysts is referred to under the head of TUMOURS.

J. F. PAYNE.

## D

**DACTYLITIS** (δάκτυλος, a finger).—A term meaning inflammation of the finger. It is applied to syphilis and struma of the part, as in the terms *dactylitis syphilitica* and *dactylitis strumosa*.

**DANDRUFF**, or **Dandruff** (from Celtic *ton*, skin; and *drwg*, foul).—Scurf of the head (see **HAIR**, Diseases of). Dandruff is met with in pityriasis, chronic eczema, and psoriasis of the scalp.

**DANDY FEVER.**—A synonym for Dengue. See **DENGUE**.

**DARTRE** (Fr.).—This term is the French equivalent of the word *tetter*, and is applied to a variety of cutaneous diseases, without strict limitation.

**DAVOS-PLATZ**, in North Engadine, Switzerland, an Alpine valley at an altitude of 5,177 feet. Well sheltered; atmosphere still and cold. A winter health resort, particularly for cases of phthisis. See **CLIMATE**, Treatment of Disease by; and **PHTHISIS**.

**DAY-BLINDNESS.**—A disorder of vision, characterised by the patient being unable to see in the daylight; called also hemeralopia. See **HEMERALOPIA**; and **VISION**, Disorders of.

**DEAFNESS.**—Loss of the sense of hearing. See **EAR**, Diseases of; and **HEARING**, Disorders of.

**DEATH, Modes of.**—The proximate causes of death, whether resulting from natural decay, disease, or violence, may be reduced in ultimate analysis to two, namely, first, cessation of the circulation; and, second, cessation of respiration. On the continuance of these functions, and particularly of the former (if specialisation is possible where all are essential), life of the body as a whole, or of the individual tissues and organs, depends. These functions may cease from causes directly operating on their mechanism, but they may also be brought to a standstill by causes operating indirectly through the nerve-centres which regulate them. Hence it is usual, in accordance with Bichat's classification, to describe this as a third mode of death; so that we speak of death beginning at the *heart*, death beginning at the *lungs*, and death beginning at the *head*. This classification is convenient; for though death beginning at the head is, in reality, death from failure of the respiration or circulation, or of both, through paralysis of the vital nerve-centres, yet the affection of the nervous system is the primary fact, and the phenomena are sufficiently distinct and characteristic to require separate consideration. It must, however, always be borne in mind that, owing to the interdependence of all the vital functions, there is no such sharp line of demarcation, in reality, as we, for convenience sake, make in theory between the various modes of death. The failure of the circulation, however, seems the ultimate factor in the

<sup>1</sup> *Dermoid Tumours*. Bland Sutton, 1889.

extinction of life, as cases are sometimes met with (of cerebral origin—tumour, &c.) in which respiration ceases and the pulse continues for some comparatively prolonged time, and, indeed, if artificial respiration be resorted to, the heart will continue beating for a long period (an hour or more), the reverse condition not being observed. The suddenness of the death is also in direct ratio with the rapidity of interference with the heart's action. In pure asphyxia it is comparatively slow as compared with that from heart disease or stoppage, and, indeed, ends fatally only by producing that result.

**I. Death from failure of the Circulation.**—This may be (1) sudden, as in *syncope* and *shock*; or (2) gradual, as in *asthenia*.

(1) *Sudden failure of the Circulation.*—As the circulation of the blood depends on the difference in the pressure in the arteries and veins, the circulation will be brought to a standstill by any cause which annihilates, or very greatly lowers, this differential pressure. The cause may be in the heart, or in the vessels, or in both.

(a) *In the heart.* As the action of the heart is the chief factor in the maintenance of arterial tension, any organic or structural disease of the heart, rendering it incapable of propelling its contents into the arterial system, will naturally result in cessation of the circulation, and death. Under this general head are to be classed all diseases of the heart and its annexes.

But, apart from structural disease, the heart may suddenly be made to cease through nervous influence. The heart may be inhibited, or be made to cease finally and for ever, either by central causes, such as violent emotion, or a blow on the head, and probably in this way in the sudden death often observed in cases of cerebral abscess and tumour; or by reflex inhibition, as in the case of a violent blow on the epigastrium, or sudden irritation of the sensory nerves of the stomach, as in corrosive poisoning, and even in the ingestion of a large draught of cold water when the system is overheated.

Death from sudden cessation of the heart's action is death from *syncope*. Momentary cessation of the heart's action is transient *syncope* or fainting. There is sudden loss of consciousness, due mainly to the cessation of pressure in, and anæmia of, the cerebral centres.

(b) *In the vessels.* Rapid fall of the blood-pressure, and cessation of the circulation, will naturally be brought about by rupture of the vessels, either from injury or disease, causing death by hæmorrhage; or by occlusion of the pulmonary artery, which seems a commoner cause of sudden death than is usually believed. But, besides actual rupture of the vessels, the vascular area may

in certain conditions become so enlarged or dilated, that we may practically have death from hæmorrhage without any loss of blood externally. This is what we observe in death from *shock* or *collapse*. In certain conditions, such as that resulting from blows on the abdomen, the vascular area of the abdomen and viscera may become so dilated as practically to retain almost the entire volume of blood in the body. Hence, even though the heart may be acting, yet the circulation throughout the body generally, and especially in the extremities and superficially, is practically *nil*. The individual may, however, retain his consciousness, and thus he differs from a patient in a state of *syncope*. But very frequently, in cases of blows on the abdomen, there is not merely reflex dilatation of the abdominal vessels, but also reflex inhibition, for a time at least, of the heart, so that we have *syncope* and *shock* co-existing. The symptoms of *syncope* may pass off, leaving those of *shock* still remaining. *Shock*, like *syncope*, may be either transient or fatal.

(2) *Gradual failure of the Circulation.*—This constitutes death from *asthenia*. This is the natural termination of life, and it is also the mode of death after wasting and exhausting diseases, cold, starvation, &c. The vital powers fade gradually, while consciousness may be retained up to the last moment.

**II. Death from failure of the Respiration.**—The various ways in which the function of respiration may be interrupted, and the phenomena consequent thereon, have been described under the head of *ASPHYXIA*, to which article reference may be made.

**III. Death from paralysis of the vital nerve-centres—Coma.**—As already remarked, death beginning at the head ends by paralyzing respiration and circulation. The nerve-centres situated above the medulla and pons are not essential to life, except in so far as animal life is concerned, and the possibility of adaptation to surroundings. Diseases of the brain, however, are liable to prove fatal by indirect action on the medulla and pons through pressure, extension of inflammation, and the like. Certain poisons also, whether introduced from without—such as opium and narcotics generally—or arising within, owing to the non-elimination of waste products, as in uræmia, affect the nerve-centres, both cerebral and spinal, and not only produce unconsciousness or coma, but also paralyse the respiratory and cardiac centres.

In death arising in this manner, the individual lies unconscious, reflex action becomes abolished, and the breathing becomes stertorous and ultimately ceases, death occurring quietly or in convulsions. In death from coma, in addition to the usual phenomena of asphyxia, there is, as a rule, more or less

marked congestion of the cerebral and spinal centres.

*Management of the Dying.*—In whichever of the three ways death may commence, the management of the dying calls for careful attention on the part of the medical attendant; and requires to be specially discussed. See EUTHANASIA. D. FERRIER.

**DEATH, Signs of.**—It is not always easy to determine when the spark of life has become finally extinguished. From the fear of being buried alive, which prevails more abroad than in this country, some infallible criterion of death, capable of being applied by unskilled persons, has been considered a desideratum, and valuable prizes have been offered for such a discovery. The conditions most resembling actual death are syncope, asphyxia, and trance, particularly the last. We cannot, however, say that any infallible criterion applicable by the vulgar has been discovered, and we do not rely exclusively on any one sign, but combine several.

The most reliable sign of death is proof of *cessation of the heart's action*. This, however, is not to be inferred from mere pulselessness, for the heart may still be beating, and resuscitation may be possible, when no pulse is to be felt in the arteries by ordinary manipulation. The use of the stethoscope is necessary, implying, of course, technical skill. Though, according to Rayer, the heart cannot cease to beat for more than seven seconds without death, yet, considering the very slow and feeble action of the heart (8 to 10 beats per minute) in hibernating animals, which normally have a pulse of 80 to 90 per minute, it is well to regard a similar condition as possible in man, and to spend in doubtful cases some minutes, up to half an hour, in auscultation. The so-called cases of life continuing notwithstanding cessation of the circulation, as that of Colonel Townsend, or of the Indian Fakirs, are to be set down as altogether apocryphal, and not scientifically investigated.

To enable unskilled persons to determine whether the circulation continues or not, Magnus recommends the application of a tight ligature on a finger or toe. If the circulation has quite ceased, no change in colour is produced; but if circulation continues, however feebly, the extremity, in course of a longer or shorter period, assumes a livid tint from strangulation of the venous flow, while a ring of arterial anæmia is observable at the point ligatured.

Cessation of the heart's action, if absolutely established, renders other indications unnecessary. As accessories they are useful, but the following signs are none of them individually conclusive, taken alone. The first is *cessation of respiration*. Respiration may not be very obvious, and yet it may be going on. The popular methods, of

holding a cold mirror before the mouth and nostrils, and looking for indications of moisture; placing a flock of cotton wool on the lips to ascertain whether air-currents exist; and placing a cup of water on the chest, and observing whether the reflection on its surface moves or remains still, are all well adapted for the purpose in view.

With the cessation of the circulation and vital turgor, the skin becomes ashy pale, there is an absence of the pink colour in transparent parts when examined under the influence of a strong light (Richardson), and the tissues lose their elasticity. The eyeball becomes less tense, and the cornea becomes opaque. The pupils cease to react to light; and there is no vital reaction on the application of irritants to the skin. Though the body is dead as a whole, certain parts may continue to retain their independent vitality after somatic death. This is seen in the muscles, which may retain their electrical contractility from two to three hours after death. The existence of electrical contractility of the muscles in a body supposed to be dead indicates life, or death within the previous two or three hours, according to M. Rosenthal.

The subsequent changes which occur in the dead body not only indicate the fact of death, but aid in fixing the probable period at which death occurred. These are the following:—

(1) *The cooling of the body.*—The body after death, except under certain special circumstances, as in fatal cases of cholera and yellow fever, ceases to be a source of heat-production, and therefore is to be looked upon as an inert mass possessed of a higher temperature than the average medium, which parts with its heat according to certain physical laws. The superficial coldness of collapse, which is due to cessation of the peripheral circulation, must not be mistaken for the cadaveric coldness, for there is still an amount of internal heat which has to be parted with; and the body, cold to the touch before death, may after death rise in temperature, as the internal heat radiates. It is impossible to describe here in detail all the circumstances which modify the rate of cooling of the body; but it may be said in general that all circumstances which favour radiation, convection, and conduction of heat in inorganic bodies are equally applicable here, while the opposite conditions retard. Therefore a thick coating of adipose tissue, clothing, &c., retard cooling. The observations of Goodhart (*Guy's Hosp. Rep.* 1870) and Burman (*Edin. Med. Journ.* 1880) show that under ordinary circumstances we may assume the temperature in the axilla at the time of death to be the normal 98·4 F. Cooling occurs at the rate of 1·6° F. per hour. The rate of cooling is greater (2–4°) during the first few hours. Taking the difference

between the axillary temperature in any given case and the normal, and dividing it by 1·6, would give the number of hours that have elapsed since death.

(2) *Hypostasis*.—After death the blood gravitates to the most dependent parts, both externally and internally, giving rise to livid discolorations, termed *hypostases*. These are liable to be confounded with ecchymoses or extravasations externally, and with the results of congestion and inflammation in the internal viscera. They differ from ecchymoses in the fact that the blood is not extravasated into the tissues, but still contained in the vessels, as may be shown by an incision into the skin. So long as the blood remains fluid, these discolorations may be caused to disappear if the position of the body be reversed; they will again form in the parts which are now the most dependent. They usually occur in from eight to ten hours after death.

(3) *Rigor mortis*.—After death the muscles become stiff, giving rise to *rigor mortis* or cadaveric rigidity. It is due to coagulation of the muscle-plasma. This rigidity attacks the muscles usually in a certain definite order, beginning in the muscles of the neck and face, and gradually extending from above downwards. It gives way to putrefaction and the attendant solution of the coagulated plasma, in the same order; so that, while the upper parts of the body may be flaccid, the legs may be found rigid. It can only be overcome by tearing the tissues, and if overcome it does not return. In this it differs from cataleptic rigidity. A certain amount of mobility is still observable at the joints. In this it is unlike the stiffness of freezing, in which all the parts are equally rigid, and crackle if bent.

The period of the occurrence of rigidity, and the length of its endurance, are extremely variable, so that no definite practical rules can be laid down. It may be said generally, however, that the greater the store of muscular energy at the time of death, the longer it is before rigidity sets in, and the longer it lasts. On the contrary, the greater the exhaustion, the sooner rigidity sets in, and the sooner it disappears. Hence rigidity is longer in appearing in subjects dying suddenly in full muscular vigour, than in those dying from exhaustion. As a rule, a period of relaxation intervenes between death and the occurrence of rigidity, but in certain cases the last muscular contraction seems to pass directly into the rigidity of death. This is seen more particularly in death during great nervous excitement, as in soldiers on the field of battle, or in suicides. The same is said to occur also in death from strychnine-poisoning and in death by lightning, in which the tetanic spasm passes into rigidity.

Rigidity may therefore occur immediately on death or within a few hours. It has never

been observed to be delayed beyond a day after death. It may last from so short a time as scarcely to be perceptible, up to a week or more.

(4) *Putrefaction*.—After death the tissues undergo changes in colour, consistence, &c., by which they are ultimately resolved into their simple elements, included under the general term *putrefaction*. Putrefaction, however, may occur locally during life, and general septic changes may occur to some extent before death. The term, however, is not generally applied until the changes are clearly perceptible in alteration of colour, consistence, and smell. The first external sign is a greenish discoloration of the abdomen. Internally the mucous membrane of the larynx and trachea is the first to exhibit change in colour and consistence. The less compact tissues putrefy first, the fibrous tissues resist longer, and—in the female body—the compact tissue of the uterus resists longest of all. In process of time, however, the soft tissues become entirely disintegrated, and the skeleton is exposed and gradually falls to pieces.

The rate of putrefaction is very variable, depending partly on the state of the body itself, but mainly on external conditions as to temperature, moisture, and exposure. A combination of high temperature, moisture, and free exposure supplies the most favourable conditions for rapid putrefaction. A high temperature alone, without moisture, tends to dry the tissues, and thus to produce mummification, instead of colligative putrefaction. Moisture alone, as when a body lies in water or moist earth, tends to produce a saponification of the tissues, more particularly the fatty, with the formation of a substance termed adipocere (*see* ADIPOCERE). The course of putrefaction can be stopped by antiseptics, as in embalming, and in certain cases of poisoning, as with arsenic, as also by freezing. Putrefaction is more rapid in air than in water, and least rapid in earth. Under ordinary circumstances and average temperatures, signs of putrefaction are clearly visible on the third day after death, commencing with the green hue of the abdomen. Many months elapse before the soft tissues become entirely disintegrated. The uterus has been found fit for judicial examination as long as nine months after death, where no antiseptics had been employed. When such has been the case, however, there is practically no limit to the period of preservation—witness the Egyptian mummies, embalmed thousands of years ago.

There is still much to be learnt respecting putrefaction, and it is unsafe to lay down dogmatic rules as to how far putrefactive changes shall have advanced at a given time, for even under apparently similar conditions the most extraordinary divergences have been recorded.

D. FERRIER.

**DEBILITY** (*debilis*, feeble).—SYNON.: Feebleness; Weakness; Asthenia; Fr. *Faiblesse*; Ger. *Schwäche*.

**DEFINITION.**—The body or any of its organs is said to be in a state of debility when its vital functions are discharged with less than the normal vigour, and when the amount of activity which it displays and of work which it can accomplish is diminished. The term 'debility' is also employed in a somewhat different sense in the case of constitutional weakness of an organ, to convey the notion of vulnerability or predisposition to disease. In this acceptation, 'pulmonary debility,' for example, signifies a peculiarly delicate 'build' of the lungs, which renders them more than ordinarily liable to succumb to the causes of disease.

**ÆTIOLOGY.**—Debility is frequently constitutional and inherited; but it is more often developed after birth. It is most commonly due to impaired nutrition, whether this be prolonged and moderate, as in defective hygiene or chronic illness, or, on the other hand, rapid and extreme, as in acute disease. Such failure of nutrition, when local, may arise from the blood being deficient in quality or quantity, or possibly from some interference with the nervous supply. Another frequent cause of debility is the abuse of the affected organ. Over-use of a part leads to fatigue, and if frequently repeated to exhaustion, the chief feature of which is extreme debility, as in cases of sustained and mental exertion, or of repeated strain of the heart. On the contrary, an organ may become feeble from want of exercise. Paralysed muscles furnish the best examples of this condition, but the same may be seen in all organs after unnatural rest. Debility is more liable to occur at certain ages, such as the periods of active growth and development, and in connexion with the menopause; and it is one of the manifestations of advanced life.

**SYMPTOMS.**—The natural ability of the organs to perform their functions varies extremely with sex, age, previous exercise, and many other circumstances. Debility, or the loss of this functional power, is therefore frequently ill-defined; and, when unquestionably present, may vary greatly in different cases, from a condition in which fatigue comes on only somewhat earlier than usual, as in muscular debility, to a state in which the slightest exertion may exhaust the whole of the vital energy, and the functional life of the part may cease—as is seen in the cardiac asthenia of acute fevers, and scarcely less markedly in certain chronic diseases, such as idiopathic anæmia and Addison's disease.

Debility may be *general*, affecting the whole body; or *local*, individual organs only being involved. Speaking broadly, the symptoms of debility of an organ may be said to be chiefly two. These are, first, increased irritability, or an unnatural readiness of the part

to respond to stimulation; and, secondly, a tendency to untimely exhaustion. The phenomena of irritability and exhaustion naturally vary with the organ involved. The symptoms of muscular asthenia are few and simple; those of digestive feebleness are more complex; and in debility of the nervous system the whole of the mental processes, as well as the functions of organic life, may be involved. For a specific account of the phenomena of each of these cases, and of debility of other parts, the reader is referred to the articles upon diseases of the several organs.

**DIAGNOSIS.**—Debility pure and simple is, as a rule, easily distinguished from *disease* by the absence of all evidence of organic alteration, and especially of physical signs of anatomical change. It is more difficult to separate debility from *disorder* or *derangement*, but careful observation will generally determine in the case of pure debility that the functions are normally discharged as long as the demands made upon them are not excessive.

**PROGNOSIS.**—Debility due to acute disease may, in the absence of complications, be expected to disappear during convalescence. If the cause have been more chronic, and be less easily removed, recovery will certainly be more slow and less satisfactory. The prognosis of inherited constitutional debility, as regards its disappearance, is nearly always unfavourable.

**TREATMENT.**—Debility must be treated according to its cause. If nutrition have failed, it must be restored as far as possible; and until this can be done, stimulants and suitable tonics are indicated—especially in the case of acute disease. Rest is of the first importance in most instances; and frequently it is alone sufficient to restore the vital force. In a few cases, however, the opposite line of treatment must be followed, as in muscular debility from want of exercise or in some forms of paralysis. Where the vital activity is low from constitutional defect, age, or sex, the condition may not be remediable; and the treatment of such cases is chiefly prophylactic. The principal indication then is to secure the subject of debility against exposure to damaging influences.

J. MITCHELL BRUCE.

**DECLINE** (*declino*, I decline).—A popular name for any wasting disease; especially associated with pulmonary consumption. The word is also applied to the period in the course of a disease when the symptoms are abating; and likewise to the time of life when the physical and mental powers are failing.

**DECUBITUS** (*de*, down; and *cumbo*, I lie).—The lying posture. *Decubitus* is also the German name for bed-sore. See POSTURE.

**DEFÆCATION, Disorders of.**—On the descent of the fæces, which accumulate in the sigmoid flexure of the colon, into the rectum, the associated movements necessary for their expulsion are excited. These movements are chiefly involuntary, though influenced and controlled by the will.

**ÆTIOLOGY.**—Some of the more important difficulties interfering with the actions of defæcation arise from disorders in the *nervous system*, by which the movements are excited and directed. In injuries and diseases of the brain or cord, the controlling action of volition, especially its influence over the sphincters, is annihilated, whilst the excito-motor movements depending on the spinal cord continue. In these cases the actions of defæcation take place only when the need of expulsion arises, without any power of the patient to induce or restrain them. In injuries destroying the lower part of the spinal cord, the fæces escape involuntarily in varying quantities and at all times.

Serious troubles in defæcation may also arise from excessive as well as from weakened action of the *muscles* concerned in this function. The sphincter may be irritable or subject to spasm, and resist too forcibly the expulsive actions of defæcation (*see ANUS, Diseases of*). Or the muscular fibres of the rectum may lose their tone, and be defective in power and incapable of properly extruding the fæces. Patients thus situated are often obliged, when at stool, to use the finger to dislodge masses retained in the weakened bowel. An atonic condition of the rectum usually arises from over-distension. It may be produced as the result of accumulations, or by too free and frequent use of enemata, the quantity injected being so large as to dilate the bowel and impair the power of its muscular coat. This atonic state of the bowel is itself apt to give rise to fæcal accumulation. The present article will deal with deficient defæcation associated with such accumulation. The opposite condition is described in the next article. *See DEFÆCATION, INVOLUNTARY.*

**Fæcal Accumulation.**—**PATHOLOGY.**—Cases of this kind are not uncommon, yet the nature of the affection is liable to be overlooked. The rectum may become gradually dilated and blocked up by a collection of hard dry fæces, which the patient has not the power to expel, being unable from loss of tone in the distended bowel to overcome the resistance of the sphincter to the passage of so great a body. Some indurated lumps from the sacs of the colon, on reaching the rectum, perhaps coalesce so as to form a large mass; or a quantity accumulated in the sigmoid flexure, on descending into the lower bowel, becomes impacted there. In several instances a foreign body has been found in the centre of the mass. The persons most subject to these troubles are those enfeebled by age or

disease, especially women. They may also occur in infants who have been operated on for imperforate anus, when the artificial aperture contracts, or is left too small for the free passage of the fæces. In these cases the distension of the bowel is sometimes excessive, and its expulsive functions are seriously impaired and weakened.

**SYMPTOMS.**—Such a collection gives rise to considerable distress, producing constipation, a sensation of weight and fulness in the rectum, tenesmus, and forcing pains which women liken to those of labour. In cases of some duration, where the hardened fæces do not quite obstruct the passage, they excite irritation and a mucous discharge, which, mixing with recent fæculent matter passing over the lump, causes the case to be mistaken for diarrhœa.

**TREATMENT.**—Injections have no effect in softening the indurated mass: they act only on the surface, and return immediately, there being no room for their lodgment in the bowel. The practitioner on passing his finger finds the rectum blocked up with a large lump, which feels almost as hard as a stone. In such cases the only mode of giving relief is by mechanical interference. The mass requires to be broken up and scooped out—an operation which may require the use of a cocaine suppository, or the administration of an anæsthetic. After the breaking up and extraction of the larger portions, injections of soap and water will be sufficient for the removal of the remainder.

T. B. CURLING. FREDERICK TREVES.

**DEFÆCATION, Involuntary.**—Under normal circumstances the fæces are retained within the rectum by the closure of the sphincter ani. When defæcation takes place, the sphincter is relaxed; and there is increased peristalsis of the lower bowel and pressure on the intestines, from forcible contraction of the expiratory muscles with the glottis closed. The nerve-governance of these three associated phases of the act is different in each case. The contraction of the abdominal muscles is mainly due to an effort of the will. The activity of the colon and rectum is reflex, from irritation of the accumulated fæces. Lastly, the relaxation of the sphincter depends on the inhibition of the tonic centre in the lumbar enlargement of the spinal cord; such inhibition being brought about either in a reflex manner from the rectum or directly from the cerebral centres. It is obvious that the relaxation of the sphincter is the most important stage in the act, for until that takes place no discharge can occur. Up to a certain point the increased peristalsis and pressure on the bowels may be resisted by a voluntarily increased contraction of the sphincter, but at a certain stage the inhibiting influence is exerted, and relaxation results. Since this influence is only in part under the

control of the will, it would follow that the chief causes of the involuntary discharge of the fæces are to be found in those conditions which diminish the normal tonicity of the sphincter. At the same time, any circumstances which may increase the pressure of the abdominal muscles, or the activity of the bowels, much beyond what ordinarily occurs, may lead to an involuntary discharge.

**ÆTIOLGY.**—The causes of involuntary discharge of fæces may be discussed in the following order:—

1. *Violent contraction of the expiratory muscles.* This cause of involuntary defæcation is such as may be induced by strychnine-poisoning. It is of rare occurrence in tetanus.

2. *Increased peristaltic action of the intestines.* Increased peristalsis is chiefly dependent on causes of irritation situate in the bowels themselves, such as inflammation or ulceration of the walls; irritating contents; or worms. Extreme fluidity of the fæces is frequently sufficient to induce their partially involuntary discharge, and is noticeable in the looseness sometimes associated with accumulation of fæces in the lower bowel, and the diarrhœa of infants and children.

3. *Abnormal relaxation of the sphincter ani.* As already said, the previously mentioned causes are powerless to produce the discharge of the fæces until the sphincter yields; and how far the sphincter may relax as a result of their efforts, or independent of them, is not easy to determine. The nervous influence emanating from the lumbar centre which normally determines the tonic state of the sphincter may be inhibited by various causes:—

a. *Reflexly.* Reflex inhibition of the sphincter ani may arise from such causes as worms, fissure of the anus, or calculus vesicæ. It is quite true that the immediate result of irritating the sphincter is to determine in a reflex manner an increase of its contraction, as may be experienced in introducing instruments into the rectum; but it would also seem that at a certain point the irritation may lead to an arrest of the tonic influence, and so allow the sphincter to yield, and this is particularly the case with affections of the bladder.

b. *From cerebral disease.* That certain emotional conditions may lead to involuntary defæcation is well known, and that a similar result follows some diseases of the cerebral centres is not an uncommon event. The paralysis of the sphincter which occurs under these circumstances is brought about by inhibiting the normal tonic stimulus discharged from the lumbar centres. Involuntary evacuations frequently occur in epileptic fits; in states of profound coma induced by apoplexy, or by opium- and other forms of poisoning; and in death by hanging or suffocation. Its occurrence can scarcely be regarded as in-

dicating lesion of any one part of the cerebral centres, but rather as a result of general brain-states. It constitutes a troublesome complication in such chronic forms of brain-disease as general softening, paralysis of the insane, &c.

γ. *From disease of the spinal cord.* The relaxation of the sphincter may of course be produced by disease or injury of the lumbar enlargement of the spinal cord. Inasmuch as it is from the cells of this region that the normal tonic influence is understood to issue, destruction of the nervous tissues can readily be understood to prevent the origination of such stimulus to contraction. Certain lesions also above the lumbar enlargement may lead to involuntary passing of fæces by interfering with the cerebral control of the sphincter. It is noticeable that diffused changes in the substance of the cord, such as acute or chronic myelitis, intra-spinal hæmorrhage, and compression, are far more frequently accompanied by paralysis of the sphincter than are the scleroses of a 'systemic' or 'columnar' character—e.g. anterior polio-myelitis, lateral sclerosis, progressive muscular atrophy, or inflammatory affections of the spinal meninges.

δ. *From local lesion.* The control over the sphincter may be lost from injury to the muscle itself. This occurs in laceration of the perinæum, involving the lower end of the bowel; sometimes it is the result of surgical operation, such as deep division of the sphincter in connexion with fistula.

**TREATMENT.**—No direct treatment of incontinence of fæces is of avail, beyond removal, when possible, of the cause. This may be done with success when the involuntary discharge depends on the presence of some local irritant, such as worms or fæcal impaction. As a distressing complication of certain diseases of the nerve-centres, which are too frequently incurable, little remains to be done for it beyond adopting such measures as will permit of the escape of the discharge with every regard to cleanliness.

W. H. ALLCHIN.

**DEFERVESCO** (*de*, down; and *fervesco*, I grow hot).—The decline of fever, characterised by a fall of temperature and of pulse, and by other phenomena. See FEVER.

**DEFORMITIES.**—See MALFORMATIONS.

**DEFORMITIES OF THE CHEST.**  
See CHEST, Deformities of.

**DEGENERATION** (*degener.*, unlike one's race; out of kind).—SYNON.: Fr. *Dégénérescence*; Ger. *Entartung*.

**DEFINITION.**—The word 'degeneration,' meaning etymologically change or deterioration of kind, is used in pathology for any process by which a tissue or substance becomes

replaced by some other, regarded as less highly organised, less complex in composition, of inferior physiological rank, or less suited for the performance of its original functions. While some change for the worse is thus the essence of degeneration, there is great variety in the mode by which this change is effected. It may be by direct chemical *metamorphosis*, as of albuminous into fatty material; by *infiltration* of the tissues with some new material, as in albuminoid degeneration; by *deposition* of some foreign substance, such as lime salts, in the tissues; or even by *substitution* of a newly formed tissue, inferior to the original in organisation or in functional efficiency, as in what is called fibroid degeneration. The degenerative process may be in certain circumstances any one of the above processes. Degeneration is very closely connected with atrophy, since on the one hand it is often caused by imperfect nourishment, and on the other hand may be a stage in progressive wasting; so that it may be difficult to draw the line between the two.

**SUMMARY.**—The following kinds of degeneration may be recognised: *albuminoid, fatty, mucoid or colloid, parenchymatous, calcareous, pigmentary, and fibroid*, with possibly one or two minor varieties of less moment. The two first-mentioned are described elsewhere. See ALBUMINOID DISEASE; and FATTY DEGENERATION.

**1. Mucoid: Colloid.**—This kind of degeneration is in one sense a physiological process, since it is probably by a partial transformation of the protoplasm of epithelial cells into mucin that the secretion of mucus is effected.

Mucoid degeneration and colloid degeneration are sometimes distinguished. We are unable to recognise any difference except in situation, and this distinction is better expressed in other words. The process consists in the transformation of portions (usually albuminous) of the tissues into a semi-transparent homogeneous material, varying in consistency from fluid to a gelatinous solid, and consisting of altered albuminates with variable proportions of mucin, a substance allied to albumin, but differing in its entire insolubility in acetic acid and its solubility in alkalis. All masses of gelatinous appearance have not this composition, since the colloid material which fills some ovarian cysts, that of renal cysts, and probably that found in some other cases, is said to contain no mucin. The thyroid gland when enlarged and cystic, as in one form of bronchocele, is a striking instance of colloid degeneration. The enlarged cystic vesicles become filled with colloid material, which plainly results from a transformation of the epithelial elements, and possibly also of some albuminous exudation in the original vesicles. Small masses of colloid material first appear in the cells,

which become confluent into homogeneous masses. In colloid cancer a similar process appears to take place, but it is rather synchronous with, than subsequent to, the growth of the tumour. The alveolar spaces, which in other forms of cancer are filled with cells, here contain colloid material resulting from the metamorphosis of cells; and every transitional stage, from the epithelioid cancer-cell to a homogeneous translucent mass, may often be met with. The stroma is unaffected, and remains fibrous. The gelatinous material of colloid cancer is stated to contain more mucin than that of the enlarged thyroid. It is instructive to notice that this form of cancer usually occurs or commences in parts where epithelium is present, which undergoes the mucous transformation and secretes mucus, as in the stomach and intestines. When colloid or mucoid transformation affects tissues of the connective tissue group, it is the intercellular substance which appears to be chiefly affected. This change is seen in the mucoid softening of cartilage which sometimes occurs in old age, where the chondrin undergoes chemical change, and the intercellular substance softens into a diffuent or liquid substance containing mucin. The so-called mucous tissue, which forms the umbilical cord and the vitreous body of the eye, as well as certain fetal structures, consists essentially of a reticulated connective tissue with mucous intercellular substance, and the same tissue forms the new-growth called myxoma, which may therefore be regarded as formed by mucous transformation of connective tissue. Its cells are quite unaffected by this change, being either fixed stellate connective-tissue cells, or migratory lymphoid corpuscles. This view explains how portions of other tumours, as sarcoma, enchondroma, and lipoma, are often found to have undergone myxomatous degeneration. All these mucoid or colloid substances contain mucin with albuminates.

**2. Parenchymatous.**—**SYNON.**: Granular Degeneration; Cloudy Swelling.—This is a peculiar change met with in some epithelial structures, especially liver and kidney cells, and muscular tissue, occurring only in the course of some infective febrile diseases, especially typhus, enteric fever, scarlatina, diphtheria, and pyæmia. The histological elements are found after death to have lost their transparency, and to be filled with minute granules, so that the general appearance is not unlike that of fatty degeneration. The naked-eye appearance of the organs is also not dissimilar: they are pale, dull, and opaque-looking. This change has been thought to be the precursor of fatty change; but, whether this be so or not, it is at once distinguished by the solubility of the granules in acetic acid, and their insolubility in ether. The cause of this degeneration has been asserted to be simply high temperature; still

it is not found in all febrile diseases. It has also been regarded as a *post-mortem* change, which is possible, but still this implies some abnormality in the tissues during life.

Another change which occurs in febrile diseases is *waxy* or *vitreous* degeneration of the voluntary muscles. They are found after death with little or no striation, and the myosin irregularly coagulated in lumps. That this is a change occurring after death there can be no doubt; while it is equally clear that this abnormal coagulation shows some abnormality of composition to have existed during life.

3. **Calcareous.**—Calcareous degeneration consists in the deposition of calcareous particles in the elements of a tissue, or in some inflammatory products previously formed. It is more appropriately called *calcareous infiltration* or *deposit*. When the normal tissues are thus infiltrated, there is not of necessity any other alteration in the tissues themselves, though the process generally indicates retardation of the circulation or arrest of tissue-metamorphosis. In the case of inflammatory products, new-growths, and parasites, as well as in other cases, the calcareous deposit follows on partial necrosis or local death. It is, therefore, if not a degeneration, the consequence or accompaniment of degeneration. See DEPOSITS.

4. **Pigmentary.**—Pigmentary degeneration is a name which has been given to the changes produced in a tissue or organ by the deposition or formation of pigment. It is very doubtful whether this should always be described as a degeneration, since the change does not necessarily diminish the vital activity of the part, lower its physiological rank, or involve a simpler chemical or anatomical composition. Pigmented tumours do not show less vitality than others, nor is excessive pigmentation of the skin, or any organ where pigment normally occurs, necessarily an accompaniment of degeneration. The colouring matter in this case is the normal pigment called melanin. An entirely different kind of pigmentary change is that which depends upon the extravasation and breaking up of red blood-discs, the hæmoglobin of which becomes converted into a simpler form of pigment, such as hæmatoidin or some other. The pigmentation of the spleen and liver from intermittent fever, and that which is the consequence of chronic venous congestion, are of this kind; and are often the accompaniment of fibroid induration, thus forming part of a degenerative process. Pigmentation in general must not, therefore, be identified with pigmentary degeneration.

5. **Fibroid.**—Fibroid degeneration is the name given to a process frequently met with, in which the original tissue becomes replaced by a form of connective tissue. It is also called *fibroid substitution* or *fibroid change*. In the early stages of this process

we find the tissues penetrated with numerous cells of the lymphoid type, which become slowly organised into connective tissue—at first of the cytogenous form, and rarely very vascular. The infiltrated lymphoid cells are probably chiefly derived from the blood-vessels; but some may be, as theory teaches, the descendants of tissue-cells. The process is an essentially chronic interstitial inflammation (see INFLAMMATION). Since the final result of the process is that tissue of less physiological value is substituted for the original, the process may be described in general terms as a degeneration, though it is not an actual metamorphosis of tissue. It finally leads to induration, contraction, and partial atrophy. J. F. PAYNE.

**DEGLUTITION, Disorders of.**—**SYNON.:** Disturbances of Swallowing; Fr. *Troubles de la Déglutition*; Ger. *Störungen des Schluckens*.

Before describing the disorders of deglutition or swallowing, it is necessary to state briefly in what this physiological act consists, and how the process is performed.

**PHYSIOLOGY OF DEGLUTITION.**—The act of deglutition is commonly divided into three stages. The first is a voluntary effort, accomplished by means of the tongue and the muscles of the cheeks and mouth, as far back as the anterior arch of the fauces. The second stage is an involuntary act, though certain voluntary muscles are engaged in effecting it. It is accomplished by the action of those muscles the duty of which is to retract the tongue, to raise the larynx and close the glottis, to lift the soft palate, to contract the fauces and bring the tonsils in contact with the bolus of food, to close the posterior nares, and to raise and contract the pharynx. Then the food passes into the œsophagus or gullet, when the third stage is entered upon; and as the morsel passes into this tube, a progressive undulatory or peristaltic movement of the gullet is produced, by which the bolus is propelled into the stomach.

**DEFINITION.**—Any condition which interferes with the perfect integrity of this physiological process constitutes a disorder of deglutition. The general term which is applied to this condition is Dysphagia or *deglutitio impedita*, as it is sometimes termed. But, in actual fact, such conditions will be found to be dependent for the most part on some other morbid state of the structures immediately concerned in the act of swallowing, or of those in close proximity to them. Yet, although dysphagia must, as a rule, be regarded merely as a symptom of some more or less serious disorder, still it may be convenient and useful to examine the subject somewhat more in detail than can be done in the consideration of those affections in which it frequently plays so prominent a part.

**ÆTIOLOGY.**—All affections of the throat modify in some way the power of swallowing, and render the act of deglutition painful and difficult. Thus:—1. We meet with it as one of the symptoms in acute catarrh of the pharynx, in tonsillitis, and in ulceration of the throat. 2. Similarly, diseases of the larynx may give rise to disorders of deglutition; such as laryngitis, inflammation of the perichondrium, and laryngeal polypi. 3. Specific diseases—for example, phthisis, syphilis, cancer, scarlatina, measles, and croup—are another fertile cause of difficulty of swallowing, owing to their affecting the throat in various ways. 4. So also are nervous affections—for instance, post-diphtheritic paralysis, hysterical disorders, general paralysis of the insane, progressive muscular atrophy, and glosso-pharyngeal paralysis. 5. Affections of the salivary glands, such as parotitis, may interfere with deglutition. 6. Œsophageal disorders, whether functional, or causing organic obstruction, are important causes of dysphagia. 7. Difficulty of deglutition may result from pressure upon some part of the passage, as by an aneurysm of the thoracic aorta, a solid tumour, whether malignant or benign, or a retro-pharyngeal abscess. 8. It may be set up by the character of substances swallowed—*e.g.* when these are irritant, corrosive, or very hot articles. All these causes, though in different degree, offer some impediment to the act of deglutition.

**SYMPTOMS.**—Although difficulty in the act of swallowing is the essential symptom in many and various affections, yet this differs greatly in degree, as well as in the attendant phenomena, according to the pathological condition of the parts involved. Thus, when irritation of any kind is met with in any part of the track through which the bolus of food has to pass, then the act of deglutition is attended merely with more or less pain, which in such cases constitutes the sole difficulty in the process. When, however, the calibre of this portion of the alimentary canal is reduced by disease affecting its own structure, or when it is encroached upon by morbid growths or other disease in its immediate vicinity, a mechanical impediment is set up, which necessitates a certain amount of voluntary effort to accomplish the act. This supplementary aid is usually sufficient to propel the bolus onwards; and deglutition, though slower than in health, and usually attended with pain, may be successfully performed. It occasionally happens, however, that the obstruction is so great as to prevent the passage of at least the larger portion of the food downwards, and regurgitation takes place through the mouth or nostrils.

A similar result is brought about when paralysis affects any portion of the muscular structures concerned in the act of swallowing, but obviously in a different manner. For example, in post-diphtheritic paralysis, in

consequence of the implication of the soft palate and neighbouring structures in this loss of power, the food, instead of passing into the gullet, returns through the posterior nares.

The dysphagia occasionally observed in hysterical persons, and which appears to partake of the nature of spasm, differs essentially from those forms already described, in the fact that it is not a constant phenomenon, and that it is but one manifestation of the neurotic temperament.

**TREATMENT.**—This will manifestly depend upon the recognition of the cause which gives rise to the impediment in swallowing. Cases of simple catarrh of the mucous membrane of the throat, and those produced by the action of irritant substances generally, yield, after a short interval, to the use of bland articles of diet and demulcents, such as olive oil, milk, linseed tea, &c. It must, however, be borne in mind that permanent stricture of the œsophagus may be the result of causes such as those last mentioned. Of course, when abscess is the cause of the dysphagia, the evacuation of its contents will give immediate relief. In that form of dysphagia dependent upon diminution of the calibre of the œsophagus, the question of its treatment by the use of bougies or stomach-tubes should be considered. *See* ŒSOPHAGUS, Diseases of.

The dysphagia dependent upon specific disorders of the larynx, such as that occasioned by phthisis, syphilis, or cancer, may often be greatly mitigated by the use of warm medicated sprays containing sedative drugs, such as bromide of ammonium, opium, or chlorine water; a 15 or 20 per cent. solution of menthol in liquid vaseline or olive oil, injected into the larynx and pharynx; also a 4 per cent. solution of cocaine, &c. In cases acknowledging a nervous origin, the treatment must bear reference to the general nervous disorder of which the dysphagia is but a symptom. Thus, hysterical dysphagia may be speedily removed by the application of galvanism in the neighbourhood of the œsophagus. Post-diphtheritic dysphagia usually disappears as the health of the patient improves, and is to be treated by the administration of nervine tonics, such as strychnine, iron, and quinine.

The food should be of semi-solid consistence, concentrated, and small in bulk—*e.g.* iced milk, cream-ice, jellies, switched egg, or the unbroken raw egg, custard, and oysters.

C. MUIRHEAD.

**DELHI SORE OR BOIL.**—**SYNON.:** Aleppo Evil; Mycosis Cutis Chronica (V. Carter); Lupus Endemicus (Lewis and Cunningham); Oriental Sore (Fox). *Fr. Bouton d'Alep; Ger. Beule von Alep.*

**DEFINITION.**—An indurated, indolent, and very intractable sore; papular in the early,

encrusted or fungating in the advanced stages; spreading by ulceration of skin; single or multiple; and often occupying extensive surfaces of the exposed parts of the body, such as the face, neck, and extremities. It is capable, if inoculated, of reproducing the disease; and it also affects dogs and horses.

**GEOGRAPHICAL DISTRIBUTION.**—This disease occurs in India, especially the North-west Provinces, Punjab, Cabul and Scinde, Persia, Arabia, Crete, the Sahara of Africa, perhaps China, and doubtless wherever certain peculiar conditions of soil and hot climate coexist; for example, an epidemic lately (1889) prevailed in Greece. Though called Delhi boil, it is neither a furunculus, nor is it peculiar to that city. The Scinde boil, the sores of Roorkee, Multan, Lahore, Meerut, other crowded Indian cities, and Aden, are probably only varieties, if not identical. The same may be said of the Bouton d'Alep of Biskra, Bussorah, Baghdad, and Crete. Slight differences may exist, but essentially they are the same disease. The Yeman and Cochin China sores are probably varieties, as are other indolent indurated and intractable sores occurring in persons of impaired health, residing in hot and malarious climates, who use certain waters, and in whom there is neither syphilitic nor strumous taint.

**ÆTIOLOGY AND PATHOLOGY.**—Drs. Fleming and Smith, V. Carter, and Lewis and Cunningham give the best account of the disease. Though called a local disease, it is probable that the state of the health has much to do with its production, certain conditions of climate, soil, and especially of drinking-water being also concerned. Furunculi of a severe and painful though different character are prevalent in hot climates at certain seasons of the year, in enervating and malarious climates like India, especially after the rains, *i.e.* towards the termination of the most exhausting season, when the vital powers have been depressed during the preceding months, and the functions of the liver and spleen are impaired. The blood, imperfectly elaborated, and not freed from excrementitious matter, is then in a condition in which it not only ministers imperfectly to nutrition, but is prone to fibrinous coagulations, which cause capillary embolism, giving rise to local starvation and death of minute portions of areolar tissue in or under the integument. These result in suppuration, which is set up for the purpose of getting rid of the dead fragment or core. An analogous, though perhaps not precisely similar, pathological condition may be concerned in the causation of the Delhi sore, and is not incompatible with an otherwise fairly good condition of the general health. Water, soil, food, bites or stings of insects, parasitic micro-organisms, insanitary conditions, such as exist in crowded native cities, have all been charged with causing the disease. Improved hygiene, planting of trees, and change of water, food, and locality,

have all been credited with benefit in the treatment of it. The facts that this peculiar form of sore manifests itself under similar climatic conditions in other parts of the world, which, it is to be noted, are generally those of the more arid regions, and that it occurs most frequently at the most exhausting season, seem to point to a constitutional state as a predisposing cause.

The disease is not confined to human beings. In Delhi it has been observed that dogs are very liable to be affected, especially in the nose, and this, from the position of the sore, has been adduced as strong evidence in favour of the theory that it is due to the presence of a parasitic organism which finds its way there from the water. In some districts other animals are affected; and it seems probable that the indolent, indurated, and intractable sore that horses are liable to in India, called *Bursattie* (Rain Sore), is of the same character. Further investigation into the causation and pathology of Delhi boil is needed, especially with reference to the action of drinking-water, and the nature of the structures that form the essential constituents of the disease.

**ANATOMICAL CHARACTERS.**—When the Delhi sore is cut into, yellowish points are seen, consisting of minute cellular growths, which have been described by Dr. Smith as the ova of a parasite (*Distoma*), and by others as of vegetable origin, but are probably the result of cell-growth, connected with the hair- and gland-follicles, perhaps an abnormal development of connective-tissue corpuscles, or an imperfect form of granulation. After ulceration has disintegrated the surface, mycelium or other low forms of organism may be present; but it is a question if these be the essential cause, and not rather an accident of the disease, introduced from without. Dr. V. Carter refers Delhi boil to a parasitic organism, consisting of spheroids and mycelium, which occupies the distended lymphatic vessels in and around the sore, arranged in open and angular meshes, the free ends giving off conidia which multiply and reproduce. Pale, round or stellate granulation-cells are found; and numerous bright orange-tinted particles, arranged as spherical or ovoid groups disseminated throughout the tissues of the tumour. These, it is considered, are the fructification-stage of the fungus. Lewis and Cunningham described lymphoid nucleated cells, the products of a condition which they considered as identical with that of lupus, and which they ascribed to the action of the chemical constituents of certain hard waters; but in a more recent paper, dated 1885, Dr. Cunningham observed, in a specimen of Delhi boil which had not yet ulcerated, certain microscopic bodies, probably zoocysts or sporocysts of some monoclinic origin, which he believes to have been connected with the causation of the disease for more than one

reason, the chief being their presence in greater numbers where the greatest morbid changes had taken place, and in the water in certain localities where the disease occurs.

**SYMPTOMS.**—Delhi sore commences as a small pink and reddish papule, like a mosquito-bite, which gradually extends, generally around a hair-follicle as its centre. This is elevated, and after a time desquamates. There is itching and a stinging sense of pain; on pressure it is somewhat boggy. The progress of the disease is slow, often occupying several weeks, during which time it assumes a semi-transparent appearance, with blood-vessels ramifying near the surface. A vesicle then rises, bursts, and gives exit to an ichor which forms a crust; under this, suppuration and ulceration take place and advance until, by the coalescence of several papules and destruction of skin, an indurated sore is formed, which is either crusted over or fungated. The sore gradually invades the surrounding parts, and, destroying the integument, may give rise, especially on the face, to deformity from cicatricial contraction; and, from the irritation and the pain it causes, may, when the number and extent of the sores are large, seriously compromise the health. An ordinary boil or abrasion may assume these specific characters. The disease is regarded as contagious, and apparently may be produced by inoculation of the specific cell-matter, though not by the pus which forms on the surface.

**TREATMENT.**—*Preventive.*—Cleanliness of person, clothing, and habitation, good food, the use of pure drinking-water, and careful attention to the sanitary condition of the locality—avoiding overcrowding and contact with the disease in men or animals,—are the best means of preventing Delhi sore.

*Curative.*—The most effective measures of a curative kind are—change of locality when practicable; in some cases early destruction of the sore by the potential or actual cautery; the application of metallic astringents, iodine, or carbolic acid lotion; pressure; attention to the state of the health, and any ailment that may be present; tonics and nutritive diet, and especially wholesome drinking-water; and change to another climate.

In the advanced conditions of the disease similar measures are indicated. The sore, if too extensive to be destroyed, should be dressed with stimulating and astringent applications. Soothing measures are indicated if there is pain. Black wash, sulphate and sulpho-carbolate of zinc, copper, Gurjun oil, and lime-water, with change of climate and the use of tonics, will generally prove efficient.

JOSEPH FAYREK.

**DELIRIUM** (*deliro*, I rave).—A derangement of consciousness, characterised by incoherence of thought, and evidenced by various expressions and actions. See CONSCIOUSNESS, Disorders of.

**DELIRIUM TREMENS** (*delirium tremens*, trembling delirium).—A form of acute alcoholism, chiefly characterised by delirium and tremors. See ALCOHOLISM.

**DELUSION** (*deludo*, I deceive).—An unfounded belief in regard to some fact or occurrence which almost invariably concerns the patient, and of the falsity of which he cannot be persuaded, either by the evidence of his senses, by his own knowledge and experience, or by the declarations of others. Such delusions, when distinguished from merely erroneous judgments upon complicated or abstract questions, generally indicate insanity. See CONSCIOUSNESS, Disorders of; and INSANITY.

**DEMENTIA** (*de*, without; and *mens*, a mind).—SYNON.: Fr. *Démence*; Ger. *Blödsinn*.

**DEFINITION.**—A mental weakness, or a deficiency rather than an aberration of intellect, depending for the most part on some antecedent brain-disorder, such as apoplexy or epilepsy; or being the sequel and termination of various forms of insanity. It may also be congenital, deserving rather the name of idiocy; or it may be due to senile decay.

1. **Acute Primary Dementia.**—There is a form of insanity known as primary or acute dementia, which comes on rapidly without any preceding disorder, is accompanied by the most profound vacuity and abeyance of all the mental faculties, yet yields to treatment and disappears, leaving the patients sane.

**ÆTIOLOGY.**—The patients are young persons, boys and girls,—more frequently girls. The complaint is seldom seen in any case beyond the age of 30, and chiefly in those under 20. It seems to be a collapse of all mental power, due to great physical weakness and deficient nerve-force. Owing to imperfect development, to bad food and living, or to the patients having outgrown their strength, the mental condition becomes so weakened that, with or without some moral cause, as a fright or a scolding or something apparently more trivial, or after some illness slight or severe, they suddenly or gradually present that condition which is now to be described. If the immediate exciting cause is some mental shock or fright, the symptoms may come on rapidly. If they are due to ill-health or some protracted exhausting occupation, the access may be gradual; and if they are set down to sulkiness, temper, or idleness, the measures adopted for the correction of the latter may quickly indicate the real state of things.

**SYMPTOMS.**—Nothing can appear more hopeless than the appearance many of these patients present. The face is vacant, with a fatuous grin, and often the saliva dribbles continuously. The sufferer sits motionless and lost, or automatically wags the head,

snaps the jaws, or moves the limbs for hours together, unconscious of fatigue. Or if a limb is placed in any position, it is retained there for a time in a way that no effort of will could accomplish. There may be a repetition of some word or sentence, but all conversation is abolished, and the patient has to be fed, washed, and tended like a baby.

The physical condition of these patients is peculiar, and corresponds closely to the mental. The heart's action and the circulation are so reduced in strength that the blood in the extremities is stagnant. Hands and feet are blue with cold even in the heat of summer. In cold weather they are covered with chilblains, and great care must be taken, otherwise these will give rise to obstinate sores. The tongue is pale and flabby. The pupils are dilated. There is no rapid emaciation, for the waste here is not great; neither is sleep absent, as in mania, but it is irregular and uncertain.

**PATHOLOGY.**—The external physical manifestations sufficiently indicate the condition of the brain in these patients. It is the very opposite of that in acute sthenic delirious mania. In the latter there is an excessive discharge of nervous force, a hyperæmic state of brain, and rapid brain-circulation; the whole leading in a short time to death by exhaustion, if relief does not come. In acute dementia we see the very opposite. The brain-action is reduced to the lowest point, and the circulation is stagnant, as in the extremities, giving rise to passive congestion and œdema.

**COURSE, TERMINATIONS, AND PROGNOSIS.**—In acute dementia there is no sudden exhaustion; but death, if it occur, is caused, not by the brain-disease, but by a general failure of the bodily strength, or by some low form of lung-disease—phthisis, pneumonia, or gangrene. Death, however, in this disorder, is the exception. When taken in time and properly treated, the majority of these seemingly hopeless cases recover, and recover perfectly.

**TREATMENT.**—The treatment of acute dementia may be carried out in a family, or even at home, if means are ample, and if the necessary measures are strictly enforced. But it may be necessary to feed the patient by force, and that for a considerable time, and relations do not always care to enforce this to the extent required. Abundant nutrition is imperatively demanded in order to restore the force that is so greatly in default; and unless abundant nutrition is administered, there will be no recovery, but the patient will die, or sink into permanent dementia. There is not, as a rule, violent resistance to food, but it may be kept in the mouth without being swallowed, and care must be taken in feeding, even if a stomach-tube be not necessary. Food should be given frequently, and so a habit of taking it engendered. Stimulants—

wine and brandy—will be necessary, especially in the early stages. Equally necessary is warmth; an amount of heat is required which to those in health would be oppressive, for the greatest heat of summer fails to warm the hands and feet. Warm clothing must be provided, and the circulation aided by a short sharp shower-bath, cold or tepid, and plenty of friction afterwards. Exercise is useful for the same purpose, but this is to be taken under proper supervision, for it must not be fatiguing, and due regard ought to be had to the debilitated state of the individual. In addition to the stimulus of the shower-bath, that of electricity is of great use in acute dementia. Here, and in certain cases of melancholia, marked benefit follows the application of the continuous current. Of drugs the most useful appear to be steel and quinine. The former, in this as in almost every form of insanity, is a most valuable tonic: the choice of the particular preparation should depend upon the state of the patient at the time.

**2. Chronic Primary Dementia.**—Dementia, however, may be primary, yet may not be that just described. It may come on gradually or suddenly, without previous mental affection, but is in such cases connected almost invariably with disease of the brain. Its first and most prominent symptom is loss of memory. In connexion with apoplectic or epileptic attacks, or after years of drinking, the memory is found defective. This loss may appear quite suddenly, or may be noticed to come on gradually, being at first so slight as to cause little alarm. It may vary at different times. If a patient is kept from alcohol, the memory may gain strength; and if epileptic attacks are reduced in frequency, the same thing may happen. The prognosis in all such cases is unfavourable, for loss of memory points to decided deterioration of brain. Apart from loss of memory, symptoms of dementia or weakness of mind are occasionally found as the first indication of mental unsoundness, following a fright or shock or some severe illness. If they assume the form of acute dementia, we may have hopes that they will pass away; but if with little disturbance of the bodily health the mind becomes weaker and weaker, the hopes of recovery are small.

**3. Secondary Dementia.**—Of dementia which is the sequel of prior mental disorder, such as mania and melancholia, little need be said. It varies in degree, but it is not in our power to remove it. It may be in our power, however, to ameliorate in a great degree the condition of such patients when, as is frequently the case, they are found in a very neglected state. Their friends think that nothing can be done or need be done, and they are allowed to lie in bed, often in a filthy condition, or roam about and get into mischief for want of care and skilled

attendance. Many demented patients have far more mind than is generally imagined by the uninitiated, and can be taught to be cleanly, to take their meals in an orderly fashion, and to keep themselves tolerably neat. They are susceptible of amusement, and open to reward for good behaviour. The vital powers of demented patients are low, and they suffer much from cold. In winter their minds, like their bodies, are enfeebled, and with warm weather they recover somewhat of their energy. There is a tendency in many of these patients, especially women, to become very fat, and in this condition they are subject to bronchitis, and may succumb to acute attacks of this disorder. They require warmth and good diet, for it is difficult to make them take sufficient exercise.

Females, in the writer's experience, are more prone to drift into dementia than males. The latter present various types of chronic mania, with well-marked delusions; but, among private patients at any rate, there are fewer of the hopelessly demented than among the female inmates of private asylums. One cause of this may be that the mortality amongst males is greater, and thus fewer are left to reach the demented stage.

G. F. BLANDFORD.

**DEMODEX** (*δημός*, fat; and *δήξ*, a worm).—See ACARUS.

**DEMULCENTS** (*demulceo*, I stroke softly).

**DEFINITION.**—Substances which soften, protect, and soothe mucous membranes. They are generally of a mucilaginous character. When applied to the skin they are termed *emollients*.

**ENUMERATION.**—The demulcents in ordinary use are: Linseed-tea, Gum, Starch, Bread, Honey, Figs; Linseed, Almond, and Olive Oil; Glycerine, White-of-Egg, Gelatine, and Isinglass.

**ACTION.**—The chief action of demulcents is a mechanical one, in forming a smooth, soft coating for an inflamed mucous membrane, and thus protecting it from external irritation.

T. LAUDER BRUNTON.

**DENGUE.**—**SYNON.**: Dandy Fever (West Indies); Three-day Fever; Break-bone Fever; Fr. and Ger. *Dengue*.

**DEFINITION.**—An eruptive fever, considered by many to be infectious; commencing suddenly; and characterised by severe pain in the head and eyeballs, swelling and pain in the muscles and joints—prone to shift suddenly from joint to joint, catarrhal symptoms, sore-throat, congested conjunctivæ, and affection of the submaxillary glands. The disease may remit, and is liable to relapse.

**NATURAL HISTORY AND GEOGRAPHICAL DISTRIBUTION.**—Dengue occurs epidemically and sporadically in India, Burmah, Persia, Egypt and other parts of Africa, North and South

America, and the West Indies. Epidemic visitations of dengue, extending over wide tracts of country, occur at considerable intervals, and probably depend on certain unknown atmospheric and cosmic conditions that favour its development.

**ÆTIOLOGY.**—Dengue attacks persons of all ages, from infancy to extreme old age. Its infectious character has been deduced from the apparent transmission of the disease from person to person.

**SYMPTOMS.**—The symptoms characteristic of dengue are the presence of severe continuous arthritic and muscular pains; great debility and prostration; the occurrence of an initial and a terminal rubeoloid or scarlet rash; fever, which is subject to remissions and relapses; the possibility that convalescence may be tedious and painful, and complicated by the continuance of general cachexia, pain and swelling of joints, enlargement of glands, orchitis, weakness of eyes, deafness, visceral disease (such as diarrhoea or dysentery of a chronic and intractable character, and hepatic derangement), boils, carbuncles, and perhaps insanity. In the female, uterine hæmorrhage and miscarriage may occur.

The *invasion* of dengue is usually sudden, the patient feeling well up to the period of attack. The earliest symptom is severe pain in some joint, probably of a finger, which rapidly extends to all the other joints and bones; and this pain during the progress of the disease often passes from one joint to the other by a sort of metastasis. Sometimes there is a period of preliminary malaise, of one or more days' duration, marked by anorexia, a sense of weariness and languor, giddiness, nausea, chilliness or rigor, severe pain in the head or in the eyeballs, and pains in the body, limbs, and joints—notably of the fingers and toes. The attack is often, however, strikingly sudden, as was frequently seen in the late Calcutta epidemic, commencing with violent pains and swelling of the joints, or severe pains in the head, eyeballs, neck, and back. In some epidemics certain phenomena are more prominently marked than others.

The eruption commences on the third day. The fever is accompanied by redness of the face, which is puffy and swollen; sore-throat; congested conjunctivæ; and a general redness, like the scarlatinal rash, extending over the whole body. The tongue is red at the tip and edges, and loaded with white fur, through which the red papillæ protrude. The pulse is rapid, ranging from 100 to 120, or even 140; respiration is hurried; and the temperature rises to 103° or even 105° F. These symptoms mark the occurrence of the initial fever and rash, and endure for a period varying from twenty-four to forty-eight hours. After this the rash disappears; the fever subsides; and the remission lasts for a period of two, three, or four days. A recurrence of febrile symptoms then takes place, accompanied by a

second or terminal rash. This differs in character from the first, resembling a rubeoloid or even an urticarial eruption, often showing itself first on the palms of the hands, and in some cases resulting in profuse desquamation of the cuticle, which, however, may sometimes be so slight as to be barely perceptible. These symptoms gradually subside, leaving the patient weak, exhausted, and often still tortured by swelling and pain of the joints, especially the smaller ones, which may continue in this state for weeks, making convalescence tedious and painful. Or there may be repeated relapses, prolonging the suffering and protracting recovery.

**VARIETIES.**—The symptoms vary in different cases, as to the character of the rash, the temperature, and the muscular or osseous pains.

The *rash* not only varies considerably in colour, character, and duration, but it is sometimes almost absent; in other cases it is attended with so much hyperæmia and action of the skin that excessive desquamation results. This hyperæmia also sometimes expresses itself by hæmorrhage from the mouth, nose, bowels, and uterus.

The *fever* is sometimes accompanied by delirium, or in children by convulsions; in the latter, indeed, these occasionally initiate the disease.

Dengue occasionally assumes a *malignant* form, where the amount of poison received has been overwhelmingly large. Dr. Charles says: 'Drowsiness may have passed into coma; the temperature verges on the hyperpyrexia; the heart fails, and the lungs are œdematous; while the whole surface is highly cyanotic. These cases have been popularly termed "black fever," and are justly much dreaded.' Happily they are rare. Again, there are very mild forms of the disease, in which the patients are scarcely ill, and where it is not easy to decide as to their exact nature: 'A trifling sore-throat and slight malaise may be all you can lay hold of till the terminal rash appears to show you what you have had to deal with; and even this may not be seen.'

**COURSE, DURATION, AND COMPLICATIONS.**—The period of *incubation* of dengue is probably from five to six days; it may be a day or two more or less in some cases.

In simple and uncomplicated cases the average period for the *duration* of the disease may be taken as about eight days; but it is frequently prolonged over weeks, and recovery is slow and painful; the constitution often being so much shattered that complete restoration to strength and vigour does not occur for months. It is rarely fatal. *Relapses* are liable to be frequent, and the patient may suffer more than even a second or a third relapse before recovery.

Some of the *sequelæ* already mentioned may remain to torture the patient and retard

his recovery. Albumen is occasionally present in the urine; but it is not, as in scarlatina, especially in the cases of children, a frequent or dangerous result of the disease.

**DIAGNOSIS.**—The distinction betwixt scarlatina and dengue is well marked; though during the outset there is considerable resemblance between the two diseases. There is a high temperature at first in both, but it is more quickly attained, and is transient in dengue; in scarlatina it endures for several days, whilst in dengue the fastigium gives a temperature of 103°, or even up to 105° or 107°, and, this being attained, it rapidly declines. It is exceptional to find a temperature above 102° maintained in dengue. In scarlatina the period of decline extends over several days, and is marked by slight exacerbations in the evening. In dengue it occupies a few hours, and the temperature may even fall below the normal. The severe muscular and arthritic pains of dengue do not occur in scarlatina; and the pulse in the latter is much more rapid during the early stages than in the former.

**PROGNOSIS.**—An attack of dengue does not confer absolute protection from a recurrence of the disease, though it does so to a great extent.

**TREATMENT.**—This is a specific fever, and has to run a certain course. The treatment is simple, and if judiciously directed mitigates the sufferings, and materially aids recovery.

Neither emetics nor active purgatives are necessary. They do no good, but increase the weakness and aggravate the suffering by the muscular movements necessarily induced. Moderate action of the bowels is advisable, a warm carminative aperient, or an occasional dose of calomel, rhubarb, or colocynth being administered, especially if the bowels remain confined, to which there does not appear to be any peculiar tendency, though the evacuations may be dark and often slimy, and confined at the outset. Salines, such as the acetate of ammonium, or citrate of potassium, with nitric ether, combined with aconite, are good during the pyrexia. In cases of very high temperature (105° to 107°) Dr. Charles suggests cold sponging as beneficial; he recommends it when 105° is reached. The danger to life of such a high temperature during the intense heat of the hot months in India is great; and it is then that cold sponging or the cold bath is indicated.

Belladonna seems to confer great relief in this disease. Ten to fifteen drops of the tincture may be given; and two or three such doses, at intervals of an hour, will sometimes produce excellent effects, and afford much relief. The extract may be given if preferred, in doses of one-third of a grain; or the juice in similar doses to those of the tincture. For the pains and nocturnal restlessness, morphine or Dover's powder may be given. Liniments containing

opium, belladonna, and chloroform are serviceable as external applications to the spine, back, and joints.

Tonics, and a carefully-regulated nutritious diet, are also indicated, and depletive measures must be avoided. The tonics should be of the bitter vegetable kind, such as gentian and calumba; with these may be combined a small quantity of quinine, with a mineral acid; or, in some cases, the dilute phosphoric acid, combined with nux vomica or small doses of strychnine.

Quinine is given more for its tonic than for its antiperiodic effects; though, where there is a tendency to relapses, the judicious administration of five- or even ten-grain doses may be beneficial in arresting them and reducing temperature. Bromide of potassium is recommended by some authorities, and especially when convulsions occur in children. Alkalis, colchicum, and other remedies in use in rheumatism have been found to have little, if any, effect in relieving the pains of dengue.

As to wines, claret is probably the best, but others may be given.

For the irritation of the skin, which is sometimes very troublesome, the application of camphorated oil and the use of warm baths have been suggested.

As in so many other diseases, especially those that occur to Europeans in tropical climates, complete restoration to health is likely to be expedited and promoted by change of air; and if the cachexia be severe after a prolonged attack of dengue, return to the patient's native climate for a season is desirable.

JOSEPH FAYRER.

**DENTITION, Disorders of.**—SYNON.: Teething; Fr. *Troubles de la Dentition*; Ger. *Zahnung*.

**GENERAL REMARKS.**—The period of cutting the teeth has been always recognised as a critical time, during which the health of young children is especially liable to become disturbed; and it has been a common practice amongst mothers to attribute every illness occurring in early life, from the irritation of scabies to the distortions of rickets, to the same baneful influence. The evolution of the milk-teeth is no doubt attended with some irritation, especially as at this period the follicular apparatus of the intestines is undergoing considerable development; and we know that, on account of the impressibility of the nervous system in young children, any irritation is apt to be followed by general disturbance. It is no doubt also the case that local functional derangements are frequent at this period, but it is often unfair to attribute these *directly* to the irritation of an advancing tooth. One of the most common direct results of teething is pyrexia, which may be intense; and a feverish child is particularly susceptible to impressions of cold,

and to the irritation of unsuitable food. Catarrhal attacks coming on at this time need not be therefore the immediate result of the condition of the gum. It is at least admissible to attribute them to the ordinary causes of such derangements, acting upon a body rendered for the time particularly susceptible to injurious influences. This view is supported by the fact that diarrhœa, which is a very common complication of dentition, is especially frequent during the warmer months, when the temperature is apt to undergo rapid variations, while the dress of the child remains unchanged; and is far less common during the winter, when the temperature is more uniform, and the child is more carefully guarded against the cold.

As a rule, the first milk-tooth appears in the seventh month after birth; but dentition may begin at an earlier period. It is not rare for an infant to cut a tooth at the age of four months; and occasionally at the time of birth one tooth is found to be already through the gum. In cases where the ordinary time of teething is anticipated, a pause generally ensues after the appearance of one or two teeth, and further dentition is delayed until the usual age. Constitutional conditions influence the time of teething. Thus tuberculous and syphilitic children cut their teeth early, while in rickety children the teeth are very slow to appear.

In the majority of cases the teeth pierce the gum in the following order: lower central incisors, upper central incisors, upper lateral incisors, lower lateral incisors, first molars, canines, back molars. A child of twelve months old should have eight teeth and be cutting his first molars; and the whole number (twenty) should be through the gums soon after the end of the second year. The order given above is frequently departed from. The incisors, in particular, are often cut irregularly, and it is not rare for the molars also to appear out of their proper order. A double tooth will often be seen to precede the lateral incisors, and may indeed in exceptional cases be the first tooth to appear through the gum. The canines seldom or never precede the first molars.

Some infants suffer more than others from the cutting of a tooth, and it is not always in cases where the eruption of the teeth has been delayed that dentition, when it occurs, is attended with special inconvenience. On the contrary, in severe rickets, where the delay is great, the teeth are often cut with remarkable ease.

The second dentition begins at about the sixth year. The permanent teeth are cut with more regularity than is the case with the earlier crop. The first to be seen are usually four molars, which appear behind the last of the temporary teeth. Next come the central incisors at about the eighth year; the lateral incisors at about the ninth; the

first and second bicuspids, in the place of the temporary molars, at the tenth and eleventh; the canines between the twelfth and thirteenth; and the second molars at about the time of puberty. The last four permanent molars are cut later.

**SYMPTOMS.**—The phenomena which may be looked upon as natural to the first dentition are salivation; swelling of the gum, which becomes more and more tense, hot, and painful; slight general pyrexia, with flushing of one or both cheeks; irritability of temper; and some degree of restlessness at night. These all subside when the point of the tooth appears through the gum. The complications not necessarily attendant upon the process are high fever; inflammation of the mouth and aphthæ; vomiting (gastric catarrh); diarrhœa (intestinal catarrh); cough (pulmonary catarrh); otitis, with purulent discharge from the auditory meatus; various eruptions of the skin, with, sometimes, swelling, and even suppuration of lymphatic glands; and certain troubles of the nervous system, such as convulsions, squinting, &c.

The peculiarity of the pyrexia of dentition is its irregular character. It is often higher in the morning than at night, and varies in intensity in a remarkable manner from day to day. A temperature of 104° F. at 8 A.M. is not at all uncommon in a teething infant; indeed such an amount of fever in the morning should alone lead us to inspect the mouth, as few diseases are marked by so much pyrexia at that hour of the day. It is important in practice to bear in mind this simple cause of elevation of temperature, for any disease in a child is apt to be complicated by teething, and much needless anxiety may be occasioned by overlooking the condition of the gum. We must not, however, in every case where the gums are swollen and tense, rush to the conclusion that they are the sole cause of the symptoms, for the most serious cerebral disease may co-exist with the eruption of a tooth. Thus, to take an example: if we find cerebral symptoms to supervene in the course of dentition, we must most narrowly scrutinise their character, before passing them over as merely harmless indications of the general disturbance. Headache, delirium, vertigo, startings, twitchings, and convulsive attacks, may merely indicate functional disturbance of the brain, such as is common to many disorders, and these phenomena are not necessarily symptomatic of cerebral disease; but if the bowels become obstinately confined, the pulse slow and irregular, and the respiration unequal and sighing; and if in addition there be photophobia, with sullenness and tendency to drowsiness, we may conclude that something more than mere functional derangement is present, and that there is every reason to suspect the existence of tubercular meningitis

In the case of the second dentition there may also be digestive derangement. During this period the child is subject to gastro-intestinal catarrhs, which give rise to looseness of the bowels. He is often irritable in the day and restless at night. Night terrors are common, and he may wake up from his sleep screaming with fright at some horrible dream. Besides the discomfort due to fermentation of food and acidity, considerable loss of flesh may be the consequence of digestive derangement if long continued.

**TREATMENT.**—The treatment of the complications which occur during dentition must be conducted upon ordinary principles. Aphthæ of the mouth are readily cured by the administration of rhubarb and soda, and the application to the mouth of a solution of chlorate of potassium or borax (ten grains to the ounce) in water, and sweetened with glycerine. Perfect cleanliness is necessary, and the child's mouth should be washed out each time after taking food with a piece of soft rag dipped in warm water.

Vomiting is best checked by clearing out the stomach with an emetic of ipecacuanha wine, giving a tea-spoonful every ten minutes until sickness is produced. Afterwards, a few grains of bicarbonate of sodium may be given with one drop of liquor arsenicalis in a tea-spoonful of water three times a day. Diarrhœa should be treated on the same principle: first a dose of castor oil to remove irritating products from the bowels; then a mixture containing chalk and catechu, or oxide of zinc (one grain to the dose). If afterwards the motions continue large, pasty-looking, and offensive, and are passed too frequently in the day, one drop of tincture of opium may be added to the mixture, as there is usually in such cases too rapid peristaltic action of the intestines. In the case of either of these derangements (vomiting or diarrhœa), it is of great importance to keep the body warm, and this is most effectually done by applying a broad flannel bandage to the abdomen. The diet also should be temporarily modified, reducing the quantity of farinaceous matter that is being taken, on account of the tendency to acid fermentation of food which is set up by such a condition of the alimentary canal.

Looseness of the bowels during dentition has been looked upon by some writers as a natural method of relief to the system, and fears have been entertained of grave troubles which might ensue if the looseness were too suddenly arrested. Such fears are, however, quite groundless. A catarrhal condition of the bowels should be cured as quickly as possible, especially during dentition, for at this time the susceptibility to chills is heightened, and the danger of severe diarrhœa being set up correspondingly great. In some cases of teething, where the lungs as well as the bowels are the seat of catarrh, and there is

a risk of bronchitis, Trousseau recommends that the intestinal derangement should not be suddenly put an end to; but even in these cases a dose of castor-oil may be safely given, to remove irritating matters from the canal, for, according to the writer's experience, any irritation of the bowels is apt rather to increase than to diminish pulmonary mischief.

The favourite remedy for all disorders occurring at the time of dentition is lancing the gums, but the practice is one which ought not to be pursued indiscriminately. Unless the gum be actually swollen and tense, incising it has no object whatever, for to cut the top of the gum can have no influence in promoting the development of the tooth below. If, however, there be very much inflammation and swelling, and the child seem to be in pain, relief may be obtained by lancing, but in this case the object is merely to relieve tension. Excitement of the nervous system dependent upon the condition of the mouth can perhaps be allayed by the same means; but in the case of convulsions more benefit is to be gained by the use of warm baths, cold applications to the head, and the gentle action of a mild alterative aperient.

In the second dentition, care should be taken to keep the child's feet warm and his body properly protected from cold. Attacks of indigestion and diarrhoea must be treated by suitable remedies, and attention should be paid to the diet, limiting the quantity of starches and sweets allowed, on account of the tendency to fermentation and acidity. Night terrors, which are merely attacks of nightmare, can be cured at once in children by a mild aperient to clear away undigested food from the bowels, and by a careful diet. Sweets, starches, and fruit should be forbidden; and the child must be fed on meat, fish, poultry, milk, butter, cooked green vegetables, eggs, stale bread, and any kind of non-fermentable food suited to his age.

EUSTACE SMITH.

**DENVER**, in Colorado.—Situated 5,200 feet above the sea, on a plain backed by the Rocky Mountains. A dry, cold, clear, and bracing climate. Diathermancy considerable. Temperature: mean daily range, 24° F., showing great variation; mean temperature, 49°. Rainfall, 15 inches. A valuable high-altitude station for phthisical patients. Railway communication and accommodation excellent. For invalids the suburbs of Denver are preferable to the city itself.

**DEOBSTRUENT** (*de*, from; and *obstruo*, I obstruct).—A measure which removes obstructions, such as an aperient; or which opens the natural passages or pores of the body. See PURGATIVES; and DIAPHORETICS.

**DEODORANTS** (*de*, from; and *odoro*, I cause to smell).

**DEFINITION.**—The term 'deodorant,' although it has a more extended signification, is generally used to signify a substance that destroys offensive odours.

**GENERAL PRINCIPLES.**—Odorous bodies are essentially volatile, and those which are offensive frequently contain sulphur in some state of combination. Deodorants usually produce the effect for which they are used by causing a chemical change in bodies to which they are applied; but sometimes their action consists in absorbing and condensing odorous substances, and thus destroying or counteracting their volatility. Substances which, like charcoal, possess this latter property may, however, indirectly produce chemical changes by bringing the odorous substances into contact with oxygen in a condensed and active condition.

Deodorants may be classed as *volatile* and *non-volatile*.

**1. Volatile Deodorants.**—These all consist of substances the action of which is immediately and exclusively chemical. Being intended to act on bodies which are themselves volatile, they admit of more generally useful application than those which are not volatile.

**ENUMERATION.**—Chlorine and its lower oxides, Sulphurous Acid, Nitrous Acid and other oxides of Nitrogen, Ozone, and Peroxide of Hydrogen, are the most important members of this class.

**APPLICATION.**—In the selection and use of volatile deodorants, it is necessary to distinguish between bodies which possess the power of destroying or removing a noxious smell, and those which merely cover one smell by another. Carbolic acid, for instance, which is a valuable disinfectant, is of little use as a deodorant, although its powerful odour may render other weaker but more objectionable odours imperceptible or indistinguishable. On the other hand, the so-called chloride of lime (chlorinated lime of the Pharmacopœia), while it possesses a strong and characteristic smell itself, is capable of destroying other noxious odours, and is an excellent deodorant.

The chemical action by which noxious odours are destroyed is principally one of oxidation, and therefore the agents forming this class of deodorants are generally oxidising agents. Ozone, or active oxygen, is the natural deodorant contained in the atmosphere, which no doubt largely contributes to the destruction of noxious vapours in the air. Volatile oils, which emanate from the flowers and other parts of plants, in contact with atmospheric oxygen produce peroxide of hydrogen, and this as an oxidising agent possesses deodorising as well as disinfecting properties. The moderate and judicious use of perfumes may thus produce a beneficial

effect, although their undue employment, by hiding rather than removing what is objectionable, may be injurious to health, and cannot be recommended. The preparation called 'Sanitas' is principally a solution of peroxide of hydrogen.

**2. Non-volatile Deodorants.**—**ENUMERATION.**—Among this class of deodorants are included Charcoal, Earth, Lime, Oxide of Iron, Sulphate of Iron, Chloride of Zinc, Nitrate of Lead, and Permanganate of Potassium.

**APPLICATION.**—Although very efficient when brought into contact with the class of odorous substances referred to as noxious gases, these deodorants are less generally useful than they would otherwise be on account of their non-volatile character. Charcoal owes much of its efficacy as a deodorant to the surface-attraction and power of condensation which it possesses, by virtue of which it brings noxious gases, such as sulphuretted hydrogen, into contact with oxygen in a condensed and active state, so that they are burnt up and resolved into innocuous compounds, or compounds less noxious than those from which they are produced. Earth and oxide of iron, which, like charcoal, are used in the solid and dry, or nearly dry, state, absorb and combine with, or promote the combination of, noxious gases, producing innocuous products. Lime may be used either dry or in the state of milk of lime. The other substances named are used in the form of solution in water. Where large quantities of decomposing animal or vegetable matter are required to be deodorised, dry lime or solution of sulphate of iron (green vitriol) may be economically and advantageously used.

T. REDWOOD.

**DEPILATORIES** (*depilis*, without hair).—**SYNON.**: *Psilothron*; *Rusma*.

**DEFINITION.**—Depilatories are measures used for the destruction of superfluous hairs.

**Hypertrichosis.**—The patients who present themselves for treatment by depilation are, of course, almost always women. In the immense majority of cases the disfiguring hairs are on the upper lip, chin, neck, or in front of the ears, the annoyance and mental depression caused by them being often so extreme as to justify any procedure likely to give permanent relief, provided it is rationally employed and its limitations are properly understood. It must be carefully borne in mind, however, that in a certain number of cases hypertrichosis is only temporary, dependent perhaps on pregnancy or menstrual disorders, or associated with acne and other sebaceous affections; and that in these circumstances it may disappear spontaneously, or as the result of treatment directed to these associated conditions. As a rule, the disfigurement is first noticed at about the age of eighteen, and is

progressive till twenty-five or thirty, after which it remains permanent till the menopause, when it frequently becomes aggravated.

**ENUMERATION.**—Various caustic applications are occasionally used as depilatories. Sir Erasmus Wilson recommended the following:—Quicklime (three parts), sulphide of sodium or of barium (one part), diluted with starch (four parts). The powder, mixed with water to the consistence of a thin paste, is laid on the affected part by means of an ivory paper-knife, and allowed to remain for from five to fifteen minutes. It must then be carefully scraped off, when the hair, shrivelled and burnt, comes away with it. The skin must then be washed with water, dried, and anointed with cold-cream.

Although the immediate result of this method is sometimes satisfactory, a troublesome degree of dermatitis is generally occasioned by it. The hairs, too, always return, their roots not being destroyed, but only stimulated by the treatment; and the subsequent growth is invariably stronger, darker, and more disfiguring than the original, while considerable scarring too frequently results.

Many women keep the disfigurement due to hypertrichosis in abeyance by habitually extracting the hairs with forceps. There are many obvious objections to the procedure, but in some cases, where no other treatment is applicable, it answers fairly well; as its result, however, the growth becomes darker, stronger, and more bristly. In a certain number of cases good cosmetic results are obtained by bleaching the hair with a saturated solution of peroxide of hydrogen.

**Depilation by Electrolysis.**—The only efficacious and permanent method of destroying superfluous hair is by electrolysis. First practised by Michel, of St. Louis, U.S., in 1879, subsequently by Hardaway, G. H. Fox, and other American dermatologists, it has of late years been introduced to the continent of Europe and to this country, where, however, owing to its indiscriminate employment, too often by unscientific persons, the treatment appears likely to fall into unmerited discredit.

**INDICATIONS.**—Generally speaking, the cases in which electrolysis is most applicable are those where—(1) the growth is limited in extent, and stationary, not progressive; (2) the hairs are strong and dark; (3) the amount of downy undergrowth is slight; (4) the patient stands pain well, is sufficiently intelligent to understand the bearings and restrictions of the process, and is in a position to submit to its necessarily protracted duration. There is little doubt that downy hairs in the regions operated upon sometimes become dark and strong with undue rapidity as the result of electrolysis; but it is also more than probable that, independently of it, these hairs would ultimately, although more

slowly, become sources of disfigurement. The writer is of opinion that cases in which the growth is most abundant upon or confined to the upper lip—and, unfortunately, they form a considerable proportion of those who present themselves for treatment—are, as a rule, unsatisfactory, owing to the large number of hair-follicles there present, the extreme sensitiveness of the part, the small number of hairs which can be extracted at a sitting (seldom exceeding twelve to fifteen), and the amount of inflammatory œdema set up in the lax tissue.

**APPARATUS.**—The necessary apparatus for depilation by electrolysis comprises—(1) a reliable constant-current battery of from ten to twenty cells, the nature of the elements being a matter of indifference; (2) an absolute dead-beat galvanometer, graduated in milliampères, and preferably incorporated with the battery; (3) long, light, pliable rheophores; (4) a suitable needle-holder, connected with the negative pole of the battery, many forms of which are now made (those which have the current-interrupting apparatus in the handle are clumsy and inconvenient); (5) a fine needle made of steel or platinum, or of gold or platinum tipped with iridium—(the writer, after giving all these a fair trial, has reverted to the finest steel sewing-needles—Abel Morrall's 12's, the only disadvantage of which is their brittleness); (6) a carbon or brass cylinder covered with chamois-leather, constituting the positive electrode, and connected with the positive pole of the battery. A steady hand and good vision are indispensable on the part of the operator, all suggested arrangements of magnifying-glasses being unsatisfactory. The best of such is a watchmaker's glass mounted on a spectacle-frame.

**METHOD.**—The patient being placed in a good light, and preferably in the recumbent posture, the needle is introduced into the hair-follicle for a distance of  $\frac{1}{16}$  to  $\frac{1}{8}$  of an inch or more, the follicle being, as it were, catheterised. The experienced touch is even able to distinguish when the bottom of the follicle is reached, by a slight increase in the resistance encountered. The current is closed by the patient firmly grasping the positive electrode, previously well soaked in warm water, and a sharp pain is experienced at the moment of closure, which persists, but in a modified form, throughout the destruction of the hair. The hair may then be seized with forceps, held in the left hand; and, when destroyed, it comes away without appreciable traction. The current is then broken by the patient relaxing the grasp of the positive electrode, and the needle is withdrawn. Whilst the current passes, a little froth, evidence of the electrolytic action, wells up by the side of the hair, and an urticarial wheal forms. This soon subsides, leaving a pink, hardish papule, which lasts a

few days; whilst occasionally a minute scab forms, which may take about a week to separate. In either case a tiny white depressed scar is left, but it is usually practically imperceptible after a short time. Occasionally, however,—especially in persons of dark complexion—the scars are rather deeply pigmented, and the resulting disfigurement disappears but slowly. A current of five milliampères employed for half a minute is sufficient to destroy the strongest hairs, if the follicle is accurately struck; and from six to ten cells are usually sufficient to generate this current strength. Weaker currents are effectual in destroying finer hairs, but it is strongly inadvisable to attempt to destroy lanugo. The amount of pain experienced varies within very wide limits; it is seldom so intolerable as to contra-indicate the operation. In some cases ointments containing 10–20 per cent. of cocaine, rubbed in for ten minutes beforehand, diminish it sensibly. The number of hairs extracted at a sitting ought never to exceed fifty, and an interval of several days ought always to be observed between the destruction of hairs close together. A few recurrences necessarily take place, their number being in inverse ratio to the expertness with which the operation has been performed. They are easily recognisable, and are generally most abundant beneath the chin and on the neck, where it is difficult to determine the precise direction of the hair-follicles.

It is impossible here to dwell upon all the details of the procedure, the success of which mainly depends upon skill, patience, and experience.

J. J. PRINGLE.

**DEPLETION** (*depleo*, I empty out).  
SYNON.: Fr. *Déplétion*; L'Action de vider; Ger. *Entleerung*.

**DEFINITION.**—By the term 'depletion' is understood: (a) the unloading, or rendering less full, of that which is over-burdened or over-full, for example, portions of the turgid vascular system—as the portal vessels; or (b) excessive evacuation, causing exhaustion—as in choleraic or other severe diarrhœa.

**USES.**—Depletion, local or general, as a therapeutic agent, may be practised in a variety of affections, such as cerebral congestion, venous turgescence, engorgement of the portal system, pulmonary congestion, renal ischæmia, aneurysm, or general plethora.

**METHODS.**—The agencies whereby depletion may be produced are blood-letting, general or local; purging; vomiting; sweating; and abstinence from food and drink.

1. **General Blood-letting.**—There is no more powerful or prompt depleting agent than general blood-letting by venesection or arteriotomy. Indeed, the chief indications for bleeding are to be found where it serves a depleting purpose—e.g. in engorgement of

the right heart and venous system as a result of disease of the heart itself, or from disease of the lungs or from impaired respiratory movement; also in visceral congestion and arterial turgescence (*see* BLOOD, Abstraction of). It is seldom, however, that abstraction of blood needs to be carried to such an extent as to exert a marked depleting effect on the whole system; it is required, rather, for the relief of limited vaso-motor disturbances.

2. **Local Bleeding.**—Bleeding by means of leeches, scarification, or cupping, may serve a very valuable depleting purpose in limited congestions, as in those of the pericardium, pleura, peritoneum, lungs, eyes, kidneys, tongue, uterus, and hæmorrhoidal vessels.

3. **Purgation.**—For general depleting purposes free purging by means of hydragogue cathartics is a most efficacious agent. When it is required to give relief to turgid vessels without abstracting blood in cerebral, cardiac, and hepatic congestions, nothing depletes so readily, efficiently, and safely as watery purges. The best purgatives are elaterin, jalap, senna, scammony, sulphate of magnesium or sodium, tartarated soda, acid tartrate of potassium, croton oil, and gamboge; to which list may be added mercury, antimony, and resin of podophyllin. The great advantage of hydragogue purges is that they deplete by removing serum from the blood-vessels without the loss of red corpuscles. Depletion by means of such purges is of cardinal service in cerebral congestion. In congestion of the intestinal tract arising from hepatic, cardiac, or pulmonary disease, a mercurial followed in a few hours by a saline purge is of great service. Antimony has been mentioned in the above list because of its usefulness in combination with sulphate of magnesium and other saline purges. As it also acts as a powerful circulatory depressant, we should remember that it can be only employed when such action is permissible.

4. **Vomiting.**—Antimony, when used as an emetic, has a powerfully depressant, as well as evacuant or depletory effect; but depression and depletion are not synonymous. The lowering effects of free purging are pronounced, and, ordinarily, sufficient. Emetics may act as depletants by evacuating the contents of, or producing a flux from, the stomach and intestine; but when used with this object their depressant action is always to be borne in mind.

5. **Sweating.**—Sweating is a less effectual method of depletion, but if freely induced may, as in cases of renal disease, serve a good purpose in lowering arterial tension and assisting the elimination of retained materials. The usual modes of exciting diaphoresis are active exercise, the hot air (or Turkish) bath, the vapour bath, wet packing, nitrate of pilocarpine (*Jaborandi*), antimony, Dover's powder, and spiritus ætheris nitrosi,

or a judicious combination of these measures. Copious draughts of hot liquids often aid the action of diaphoretic remedies. The evacuant action of sweating and purging may be advantageously combined when speedy depletion is desired. The combination is valuable in certain dropsies. *See* DROPSY.

6. **Abstinence.**—General depletion may be produced by abstinence from food and drink, and this method is sometimes employed in the treatment of aneurysm.

ALFRED WILTSHIRE. JOHN HAROLD.

**DEPOSITS.**—The term 'deposit' had at one time a much wider extension in pathology than it has now. In accordance with the doctrine of morbid *crases* or *dyscrasia*, it was customary to regard cancers and all new-growths, the products of tubercular and scrofulous diseases, as well as those of the specific fevers and ordinary inflammation—in fact, almost every kind of morbid product in the body—as 'deposited' from the blood in consequence of some alteration in its composition (*see* BLOOD-DISEASE). In many of these cases the term *deposit* is still often used, even though an entirely different view may be taken of the processes leading to these morbid changes. The name remains, though the idea has departed; and this is also true of other morbid products called 'deposits.' The term *secondary deposits* was formerly used for what are now called pyæmic or secondary abscesses, from a belief that pus was removed from the original seat of disease, and deposited in distant parts. The term *atheromatous deposit* is due to Rokitansky, who described this change as due to the deposition upon the arterial wall of material precipitated from the blood. In both these cases the term seems now misleading. Again, several processes which we now call degenerations or infiltrations were formerly spoken of as deposits; for example, lardaceous, fatty, and pigmentary deposits; and although these processes may now be better described by another name, it cannot be doubted that in some of them an extraneous substance is actually deposited in the tissues. The term *fibrinous deposits* was also used for the masses now known as infarctions or blocks (as for example in the spleen or kidneys), where the appearance of a mass of extraneous material is produced by the degeneration as a mass of tissue, mixed with products of hæmorrhage, inflammation, and exudation. In quite another sense the various substances precipitated from urine are spoken of as *urinary deposits*, with which we are not here concerned.

When these exceptions are made, the present use of the word *deposit* is a limited one, but is appropriate in those cases where something different from the elements of the tissue, and especially if it be an inorganic material, is found in their substance, and

when it may reasonably be supposed that this material has been brought to the tissues by the circulating fluid and there deposited. The term is clearly inappropriate when the foreign matter is formed by some chemical change in the substance of the tissue-elements; but between such cases and those just mentioned it is very difficult to draw the line. We shall speak, in the sense just defined, of *calcareous*, *metallic*, and *pigmentary* deposits.

**1. Calcareous Deposits.**—All calcification of the tissues of the body, whether normal or degenerated, of inflammatory products, of new-growths, or of any other morbid products, appears to depend upon the deposition of lime-salts in the form of granules, this deposition taking place either within the substance of the elements, or more rarely in the intercellular substance, or, possibly, sometimes in the interstices of the tissue. Calcareous deposit takes place towards the close of life in several parts of the body, as in the walls of arteries, in cartilages and tendons, in the valves of the heart, and the crystalline lens of the eye; though in most of these cases, if not in all, some other pathological change precedes the deposition of lime. Still more frequently this change occurs in masses of dead or degenerated materials, as, for instance, in organs which have partially or wholly lost their vitality, in new-growths which have reached the stage of retrogressive change, in old blood-clots, or in products of bygone inflammation. A wasted eyeball always becomes partly calcified (sometimes ossified); tumours, such as myoma and fibroma, are especially subject to calcification; venous clots which remain long undisturbed, as in the deep veins of the pelvis, undergo the same change, and become phlebolites. Old inflammatory products, as pus and lymph, seem to become necessarily calcified if they are not absorbed; so do especially the products of chronic degenerative inflammations which have become necrotic, as seen in scrofulous lymphatic glands, and in tubercular masses in the lungs. A similar explanation applies to calcareous deposit in the walls of arteries, where the lime is generally deposited in new products which result from chronic arteritis or the atheromatous process, though lime may also be deposited in the muscular walls independently of atheroma. Necrotic masses resulting from embolic infarction are frequently calcified. Parasites of all kinds, occurring in solid organs, are liable to become surrounded by a calcified wall; a change frequently seen in hydatid cysts.

From all this it appears that calcareous deposit rarely occurs in normal healthy tissues, but is common in such parts as are dead or of deficient vitality. Its deposition must be attributed to some chemical reaction between the tissues thus altered and the lime-

salts in the blood; and it is possible that the presence of an excessive quantity of lime-salts in the blood sometimes favours the change, since deposition of lime in one part sometimes coincides with removal of it from another part. In senile decay the wasting of bones goes on simultaneously with the calcifying processes just mentioned, and in some rare cases rapid absorption of bone from special disease has appeared to be the determining cause of its deposit elsewhere by a sort of *calcareous metastasis*.

**2. Metallic Deposits.**—Other minerals besides lime-salts are rarely found deposited in the tissues, although in cases of chronic metallic poisoning, compounds of lead, silver, and copper may be found thus deposited. Zinc and mercury are less clearly traced, but probably follow the same law. The state or chemical combination in which the metals occur is not positively known, but appears to be some combination with albumen.

**3. Pigmentary Deposits.**—Pigmentation as a process is discussed in the article **DEGENERATION**, and has been shown to depend very frequently upon the occurrence of hæmorrhage and transformation of the extravasated blood. But physiological pigment, or melanin, is deposited in many parts of the body, both normally and pathologically, quite independently of hæmorrhage. Normally this is seen in the skin, the choroid coat of the eye, &c.: pathologically in the same situations, but in excessive quantity; and also in abnormal situations, as on the mucous membrane of the mouth. The arrangement of the pigment is in every case the same, forming minute black granules in the protoplasm of the cells around the nucleus. Its deposition and removal are regulated by causes as yet very imperfectly known, but are probably in some way dependent upon the nervous system.

The deposit of such substances as fat, lardaceous material, colloid, &c., is not a simple process, but depends either upon chemical metamorphosis of the cell, or on general pathological changes, which are dealt with in other parts of this work.

J. F. PAYNE.

**DERBYSHIRE NECK.**—A synonym for goitre, which is thus called from the prevalence of the disease in that county. *See* **GOÏTRE**.

### DERIVATIVES (*derivo*, I drain).

**DEFINITION.**—Medical appliances or remedies which lessen a morbid process, such as inflammation, in one part of the body, by producing a flow of blood or lymph to another part.

**ENUMERATION.**—Derivatives include Local Bleeding, Cupping, Leeches, Blisters, Sinapisms, and Setons.

**ACTION.**—The name 'derivative' was applied in ancient times under the belief that

diseases were caused by morbid humours, which might be drawn away from the part which they were affecting. It is now used chiefly to signify the diminution of blood in an inflamed part, by increased circulation in some other vascular district, either adjoining or remote from it.

T. LAUDER BRUNTON.

**DERMATALGIA** (*δέρμα*, the skin; and *άλγος*, pain).—Pain and aching in the skin. See NEURALGIA.

**DERMATITIS** (*δέρμα*, the skin).—Inflammation of the skin: a term applicable to every variety of inflammation of the integument, but especially to an acute inflammation attended with exfoliation of the cuticle and copious desquamation—for example, *dermatitis exfoliativa*, the  *pityriasis rubra*  of Devergie.

**DERMATOLYSIS** (*δέρμα*, the skin; and *λύσις*, a loosening).—Looseness or relaxation of the skin. See MOLLUSCUM.

**DESQUAMATION** (*de*, signifying separation; and *squama*, a scale).—The process of separation or shedding of the epithelium of any surface. It is of most importance in connexion with the skin in scarlatina, where the epidermis usually desquamates extensively.

**DESQUAMATIVE NEPHRITIS**.—A synonym for certain forms of Bright's disease, applied on account of their being characterised by shedding of the epithelium lining the tubules. See BRIGHT'S DISEASE.

**DETERGENTS** (*detergo*, I cleanse).

**DEFINITION**.—Substances which cleanse the skin.

**ENUMERATION**.—The principal detergents are—Water, Soap, Alkalis, Ox-gall, Milk, Vinegar, Alcohol, Charcoal, Sand, Oatmeal, Sawdust, Pumice-stone, Oil, and Borax.

**USES**.—Detergents are used to remove either extraneous dirt adherent to the skin, or epidermal scales which have accumulated upon it and interfere with its function. The chief detergent is warm water, but its action is greatly aided by such substances as soap, alkalis, borax, or vinegar, which act chemically in the removal of dirt or epidermis; or by such substances as oatmeal, sawdust, charcoal, pumice-stone, and sand, which act mechanically. Oil, or alcohol in the form of *eau de Cologne*, removes the resinous deposit left on the skin by plasters. Where the skin is tender, as in the case of the scalp, and where at the same time the detergent employed cannot very readily be removed, borax with elderflower water may be found preferable to the more irritating soaps as a means of removing scurf.

T. LAUDER BRUNTON.

### DETERMINATION OF BLOOD.—

Increased flow of blood to a part or organ: synonymous with *active hyperæmia* or *active congestion*. See CIRCULATION, Disorders of.

**DEVELOPMENT, Arrest of**.—The causes of arrest of development are in most cases still very doubtful, and for the most important theories and observations on the subject the reader is referred to the article on MALFORMATIONS. Such arrests may take place at any stage in the development of the embryo and of its organs; but only the most important of them, and the mode in which some typical examples are brought about, will be mentioned here.

**VARIETIES**.—Those which occur very early in fetal life are complex and, for the most part, incompatible with viability; whilst those which occur later often affect only one organ or a set of organs, and in some cases form no barrier to a prolonged existence. Not only must the fetus be considered, but also the placenta and membranes in which it is enclosed *in utero*; for diseases of these lead to many forms of monstrosity, either by interference with the nutrition and respiration of the embryo, as in the case of many so-called 'true moles'; or the normal changes may be checked by adhesions between them and the fetus. Persistence of the umbilical vesicle is excessively rare, but a patent vitelline duct is not uncommon, and explains many of the diverticula in connexion with the small intestines. A want of closure of the visceral laminae is the source of many deformities, from a simple fissure in the sternum, or a ventral hernia, to a complete anterior cleft, with the thoracic and abdominal viscera lying bare out of the body-cavity. In other cases the skin and muscles only may cover the viscera, or the muscles may not be developed. The thorax is closed before the abdomen, so that ectopia of the abdominal is more common than of the thoracic viscera. The abdomen, however, is sometimes closed in whilst the thorax remains open, and varying degrees of ectopia cordis result; but this is rarely complete. Epispadias and hypospadias to varying extents are further examples of imperfect fusion of the ventral laminae. These may or may not be attended with displacement or deficiency of the urinary and genital organs. Similarly, from an incomplete fusion of the vertebral laminae, the various forms of spina bifida occur; and these are generally accompanied with an excess of fluid in the spinal canal, or hydrorachis.

The arrests in the development of the cerebro-spinal centres and of the organs of special sense are very numerous. The whole brain may be wanting, or the medulla oblongata may be developed and the remaining portions missing, or any part of it may be absent or quite rudimentary. From

incomplete fusion of the bones of the skull hernia cerebri or encephalocele occurs, and this is generally complicated with hydrocephalus, though the latter is frequently found as an independent and solitary affection. Coloboma and deficiency of the olfactory, optic, or auditory nerves are well-known examples of arrested development of the organs of special sense. The special malformations of the heart and vascular system, the digestive, respiratory, and urino-genital systems, will be found described under the various organs; but reference must here be made to congenital fissures leading into the pharynx (persistent branchial clefts), to the various fissures of the face and palate, to persistent cloacæ, to the numerous forms of hermaphroditism, and to imperforate anus, as all coming under this head. Varying degrees of ill-developed extremities are common, from a diminution of number in the fingers or toes, or their coalescence, to a complete absence of one or all the limbs. Finally, ducts, vessels, and openings—such as the urachus, ductus arteriosus, umbilical vessels, and foramen ovale—which normally close soon after birth, may remain patent throughout life.

JOHN CURNOW.

**DEVONSHIRE COLIC.**—A synonym for lead colic, which has arisen from the frequency of lead-poisoning in that county, supposed to be due to the contamination of cider with lead. See LEAD, Poisoning by.

**DIABETES INSIPIDUS** (*διαβαίνω*, I walk with the legs apart; *διαβήτης*, a thing with outstretched legs, a pair of compasses, a siphon—whence the idea of free flow is derived; *insipidus*, tasteless).—SYNON.: Polyuria; Fr. *Diabète insipide*; *Diabète non sucré*; Ger. *Polyurie*. A synonym for polyuria. See POLYURIA.

**DIABETES MELLITUS** (*διαβήτης*; and *μέλι*, honey).—SYNON.: Glycosuria; Fr. *Diabète*; Ger. *Harnzuckerruhr*.

**DEFINITION.**—The term Diabetes, meaning an excessive flow of something, has been applied to the pathological condition indicated by an excessive flow of urine. It has, moreover, been almost wholly limited to the kind of malady characterised by the presence of a notable quantity of sugar in the urine—a condition more strictly described by the term Diabetes Mellitus. Another condition is sometimes seen where no sugar is to be found in the urine, which is, however, excessive in quantity. This is designated Diabetes Insipidus, or (better) Polyuria.

Diabetes is a malady more or less chronic, characterised by the persistent presence of a notable quantity of sugar in the urine, which is in most cases markedly abundant. It is accompanied by thirst, hunger, and bodily wasting. If unrelieved, it invariably tends to death. The ordinary form of diabetes is thus

to be distinguished from certain other conditions, where, for instance, a small, or hardly perceptible trace of sugar may be detected in the urine; or where, yet again, considerable quantities of this substance may be detected occasionally, and for a short time only. To this abnormal condition the term *glycosuria*, which is often also employed to describe artificial diabetes, best applies.

**GENERAL CONSIDERATIONS.**—Three important facts lie at the bottom of our knowledge of the pathology of diabetes. These are:—

I. That grape sugar is found in the healthy human body.

II. That glycogen, a substance closely allied in chemical composition to grape sugar, is also found in the healthy human body.

III. That both of these may be formed in the healthy human body.

Beyond these, certain other fairly definite propositions may be made:—

1. Glycogen is found most abundantly in the liver, inasmuch that, with due precautions, it can always be detected there: after a certain time sugar takes the place of glycogen, but the exact mode and time of this conversion are not known.

2. Nevertheless, it is fairly certain that the sugar called glucose can always be detected in the liver; still more certain that it is to be found in the blood; but

3. This sugar never appears in any notable quantity during a state of health in the urine.

4. As sugar is not to be found in any appreciable quantity in any other of the excretions, it follows:

5. That this sugar must disappear in the body.

6. It is commonly asserted, and, upon the whole, believed, that sugar is less plentiful in venous than in arterial blood.

7. From this, if true, it follows that sugar must be used up in the course of the circulation.

8. Where the combustion, or oxidation, occurs is not quite clear.

9. But it is plain that, from a fault in either direction, sugar may become over-abundant in the blood, namely:—

(a) *By over-production, or*

(b) *By diminished consumption.*

10. The over-production and the diminished consumption of sugar in the body may depend on various causes. The most notable of these are (a) an increased ingestion of saccharine material into the stomach and bowels, without a corresponding destruction; and (b) such an alteration of nerve-influence as will completely modify the relative proportions of the sugar produced and the sugar destroyed.

11. With an excess of sugar in the blood, only one easy road of egress from the body is available, that is, by way of the kidneys; but this is not a sufficient outlet when there is great superabundance in the blood. Sugar

may then be found in almost every one of the secretions or excretions.

12. With this unnatural discharge of sugar there is usually a corresponding discharge of urine, but not always.

13. Thus there may be no greatly increased flow of urine, yet the urine may be rich in sugar.

14. And yet, again, there may be a copious flow of urine without any sugar, as in *polyuria*.

15. Hence the over-production or the diminished consumption of sugar in the system has no necessary connexion with increased flow of urine.

16. Both the abnormal action of the liver and that of the kidneys seem in the main to depend on similar but not identical causes.

17. Both seem to be under the control of the sympathetic, but the special fibres are not the same as regards the two organs.

(a) In the case of the liver, the fibres seem to originate in the medulla oblongata, to descend in the spinal cord to the lower cervical or upper dorsal vertebræ, thence to leave the cord to join the gangliated sympathetic, and so ultimately to reach the liver.

(b) In the case of the kidneys, the active fibres proceed further down the spinal cord, but are ultimately connected with the great abdominal plexus, for such it may well be called, whence the fibres proceed to the kidneys.

**ÆTIOLOGY.**—The classification of cases of diabetes according to causation is in very many cases practically impossible.

As to the circumstances that call the morbid processes into play, we know very little. It is certain, however, that the disease is much more frequent among men than among women, and among the middle-aged than among the very young or the very old. The disease is very much more fatal in young adults than in those over, say, forty-five. That the disease is more rife in certain districts than in others may probably be best explained by its undoubted tendency to heredity. This heredity, as in many other maladies, is peculiar; the diabetic tendency in one branch of a family being represented in another branch by various nervous disorders, especially epilepsy and imbecility.

Of the so-called *exciting* causes there are two of the first rank, namely, injury or disease of the brain; and mental excitement, or, perhaps still more, worry. Tumours and other local brain-mischiefs sometimes give rise to a fatal diabetes. Certain mental emotions, at once powerful and prolonged, which may be epitomised in the single word 'strain,' apparently act as exciting causes of diabetes, such as continuous anxiety, long-lasting grief, or excitement followed by reaction. Certain errors of diet—such as excessive use of hydrocarbons, especially sugar, or other interference with the laws of health, may originate a fatal diabetes, especially in those who have

any hereditary tendency to the disease. It is possible that the frequency of the malady among the Jews (as noted by Seegen) may be accounted for on dietetic grounds.

**ANATOMICAL CHARACTERS.**—Many pathological conditions have been recorded as occurring in those who had been the subjects of diabetes, but we know little of its real pathology. In many cases nothing which can be directly connected with the diabetes has been found *post mortem*. Latterly attention has been mainly directed to the investigation of certain parts of the nervous system and of the liver itself. Perhaps the most reliable data for the ordinary anatomical appearances are to be found in Seegen's analysis of Rokitansky's experience, embracing 30 necropsies.

Connected with the *brain and spinal cord* various lesions have been found, such as tumours of different kinds pressing on the medulla, and softening, with or without the marks of extravasated blood. In some cases extravasation has been the only morbid change discovered. In two cases under the writer's care there were extravasations of blood in the spinal canal in the cervical and upper dorsal regions, and the same was observed in another case under the care of a colleague. In one of these there was very marked softening of the cord in the regions named. In these three cases death took place suddenly. Dr. Dickinson's theory of the origin of diabetes in lesions of the nervous system, represented by enlarged perivascular spaces, the sites of existent or pre-existent extravasations of blood with destruction of the surrounding nerve-tissue, is hardly tenable. The exploration of the sympathetic system has not been more satisfactory.

Rokitansky found (in 15 out of 30 cases) that the *liver* was enlarged, hyperæmic, and hard, of a dark-brown colour, with its acini imperfectly defined. The same conditions were present in the cases examined by the writer. When the disease has lasted a long time, the liver may be smaller than natural. The same would appear to hold good with regard to the cells themselves. Early in the disease, the cells, especially in the outer portions of the acini, are large, plump, and rounded, instead of angular, with large and distinct nuclei. They tend to assume a wine-red colour with solution of iodine, from the presence of unchanged glycogen. There are also sometimes found signs of active cell-growth at this early stage. Later the cells seem smaller, and as if undergoing pigmentary degeneration.

The condition of the *pancreas* in diabetes is highly interesting. In 13 out of Rokitansky's 30 cases, it was strikingly small, hard, and bloodless; and in many cases it has been found so shrunken and altered as to be hardly recognisable save by its connexions. Such was the case in one instance the writer has

seen, and in all his other cases the pancreas has been abnormal, usually contracted here and there, hard and knotty. In one case, however, the organ was enlarged and more succulent than usual, probably the first stage of the mischief. The occurrence of so important pancreatic changes in about one-half the cases of diabetes would seem to indicate more than a casual connexion with the disease. What this connexion really is remains unascertained. Klebs has associated the changes with disease of the celiac plexus. One result from the pancreatic mischief is inability to digest fat. This was seen in one of the cases referred to above. See PANCREAS, Diseases of.

The *kidneys* Rokitansky found diseased in 20 instances, but the changes were not uniform. Usually they presented the ordinary indications of hyperæmia, being enlarged, dark red, and full of blood. Occasionally there were signs of more extensive mischief, the substance of the kidney as well as its vessels and epithelium being involved, and the organ harder than natural. Often fatty changes occur. In one case of the writer's amyloid changes had begun in the Malpighian bodies.

The *lungs* are frequently diseased: in only 7 of his cases did Rokitansky find them normal; Dr. Dickinson only twice out of 27 instances. The changes included all stages, from acute or chronic pneumonia, to the formation of numerous cavities, or even to gangrene. In one of the writer's cases the whole of the upper lobe of one lung was converted into a huge cavity filled with solid and semifluid detritus, having no gangrenous odour. There had been no expectoration, and no hæmorrhage, though vessels were exposed.

The *stomach and intestinal canal* present little beyond the ordinary signs of recurrent or chronic catarrh—thickening, mammillation, and slaty pigmentation; erosions and ulcerations may, however, occur.

**SYMPTOMS.**—The following sketch comprehends the more characteristic clinical features of diabetes; but there are often important variations in individual cases, though a certain number of features are common to all: The patient, most likely a male between twenty and forty-five, when he comes before the physician has in all probability been suffering from the disease for some time; for it usually comes on insidiously. He may say that he has been in failing health for a varying period; that he has been very thirsty, and has passed much water, having to get up repeatedly for this purpose during the night. His appetite has been more than hearty; but his food seems to do him no good, for he has been constantly growing thinner, and he feels weak and ill. On closer examination it is found that he is daily passing as much perhaps as eight, ten, or more pints of urine, light in colour and of a peculiar sweetish

odour, of a high specific gravity, perhaps 1040°, and containing an abundance of sugar. The skin is dry and harsh; the tongue red and glazed or slightly furred; the mouth dry and clammy; the lips, teeth, and gums are covered with scanty, sticky mucus; the breath is often sweetish, or it may be unpleasant from the state of the mouth; the bowels are confined; and the countenance wears an expression of weariness and fatigue.

From this point the malady may progress in one or other of two directions. Under judicious management the symptoms may ameliorate. Often the first indication of improvement is a copious perspiration; the thirst diminishes; less urine is passed; the appetite is not so ravenous; the sugar decreases in quantity; and with it the specific gravity is lessened. Emaciation ceases, and the patient begins to regain weight. This auspicious commencement may, with time and care, end in a more or less complete return to health. Unfortunately there is another side to the picture, for, notwithstanding all our efforts, the patient often goes from bad to worse. We fail to reduce the quantity of sugar beyond a certain point. The appetite gets more and more voracious, especially for starchy articles of food, to obtain which the patient will sometimes lie or steal, and yet there is often no feeling of satiety. Sometimes the appetite fails, and then emaciation goes on still more rapidly. All sexual power and feeling have long ago been lost, the testes sometimes undergoing almost complete atrophy. The harsh, dry, and itchy skin becomes the seat of boils, or even of carbuncles. Often the sight is injured by cloudiness of the refractive media, especially of the lens, or by retinitis and other morbid changes. All this time the temperature is low, perhaps sub-normal; but towards the later stages of the malady it often rises. Such a rise indicates the accession of a formidable complication which might almost be said to be the natural termination of diabetes. This superadded mischief is a peculiar insidious kind of pneumonia, resembling acute pneumonic phthisis, and giving rise to local signs resembling those characteristic of that malady. The progress of this lung-mischief is rapid; the fever increases; and often there is irrepressible diarrhœa, sometimes of fatty-looking matter. As the end approaches, the sugar usually disappears from the urine, which may become albuminous and scanty. There may even be some œdema of the extremities. The end often comes swiftly, and without warning, by acute pneumonia, or by what, for want of a better name, we call diabetic coma, or more slowly by gradual exhaustion. After the onset of pulmonary symptoms it is never very long delayed. Such may be said to be the ordinary course of a well-marked case of diabetes. There are cases slighter, where the

history is different; but in both sets of cases there are certain symptoms, which demand further consideration than has just been given them.

*The Urine.*—The characteristic of the urine in diabetes is the presence in it of sugar in notable quantity, though this varies greatly in different cases. In the earliest and slightest forms of diabetes, small quantities of sugar may be passed now and again, as after a meal or the consumption of an unusual quantity of starchy or saccharine food; but the sugar may completely disappear in the interval, or may do so finally by the use of an animal diet. The sugar thus excreted is glucose of the kind called dextrose, from turning polarised light to the right, is readily soluble in water and alcohol, and easily ferments. When diabetic urine is allowed to stand in a warm place, fermentation soon sets in, gas being disengaged, and yeast deposited at the bottom of the vessel. The proportion of sugar to urine is usually from 8 to 12 per cent., but varies; the total quantity passed amounting to 20 or 25 ounces, or even more. Its presence in such proportion causes an increased specific gravity, though this is not invariably the case, inasmuch as it may vary from 1008 to 1060 or 1070. Along with the presence of sugar, we almost invariably find an increase in the quantity of the urine. But neither is this an invariable feature of diabetes, for sugar may exist with a normal quantity of urine, constituting the so-called *diabetes decipiens*. But in most cases there is a marked increase, the quantity passed amounting to eight, ten, or fifteen pints daily; and even the highest of these rates has been greatly exceeded. With an excessive amount of urine, its colour becomes lighter; sometimes it has a faint greenish tint, and when passed is quite clear. On standing there is no ordinary sediment, though, as already said, sporules of yeast may be deposited after a time. There is, on the whole, an excess—sometimes a large excess—of urea; and if the quantity of urine passed be small, deposits of uric acid or of the amorphous urates may appear. Very great inconvenience may arise in diabetic females, or even in males, by the arrest of saccharine urine about the external genitals, producing a raw or eczematous condition of the inside of the thighs and groins. The urine, being also almost invariably acid, is highly irritating to the raw and swollen parts. Enuresis is common, especially at night, and among diabetic children. Albumen makes its appearance sometimes in the progress of the disease, or in its later stages.

*The Digestive Organs.*—As the correlative of the unusual flow of urine we have also, as a marked and early symptom of diabetes, extreme thirst, a thirst, too, which cannot be satisfied, for apparently the more the patient drinks the greater is the thirst. This sensa-

tion is in some part due to the dry and clammy condition of the mouth, which it is difficult to relieve. Hunger, or even a voracious desire for food, is usually a prominent feature in diabetes, but is not invariably present, and in the later stages there may be complete loss of appetite, amounting to a loathing, especially for a restricted diet. It is often impossible to satisfy the intense craving for food, and should satiety be attained the sensation lasts but for a little time. The mouth is usually dry and parched, the saliva being scanty and tenacious. Often particles of food are retained about the teeth, and there putrefy, giving rise to unpleasant odours. The buccal fluid is almost always acid instead of alkaline, probably from the formation of lactic acid. The tongue is rarely perfectly natural. Seegen describes it as usually thickened and increased in volume, with fissures and glazed blood-red islands on its surface, which, however, may present a general coating. The teeth often fall out without pain, from the retraction of the gums, and are singularly liable to caries. Digestion is usually good, except during catarrh of the stomach, which is a rather frequent condition. Constipation is the rule in diabetes, often to a troublesome extent. This arises partly from the deficiency of water in the bowel; partly also from the small quantity of faecal residue from an exclusively meat diet. Diarrhoea, on the other hand, is not uncommon, and rapidly diminishes the patient's strength.

*General Symptoms.*—Emaciation is an early and marked symptom of diabetes, but not invariably so, for diabetes often occurs and persists in stout persons, without removing the obesity. These are cases of the more tractable kind, the patients being usually somewhat advanced in life. Their complete cure is seldom effected, but they do not seem to suffer greatly from the malady. Though the emaciation is in great part due to the removal of fat, and in part to the abstraction of water from the tissues, there seems to be also an actual waste of muscular substance, especially in the advanced stages of the disease. With this emaciation are associated weakness, weariness, and disinclination to exertion. These are often among the earliest symptoms of the disease, and may occur long before wasting is noticed, but increase markedly towards the close of the malady. From various causes (one being, doubtless, weakening of the heart), oedema of the lower extremities may occur, with or without albuminuria. Gangrene of the extremities, of the senile kind, has been observed.

*Respiratory Apparatus.*—With regard to the respiratory organs, a peculiar apple- or hay-like odour of the breath is sometimes observed, probably arising from the production of acetone mixed with alcohol. But the most

serious pulmonary symptoms are those of phthisis, resulting from a more or less chronic pneumonia. This mischief is usually indicated by a nightly rise in the temperature, but otherwise may remain for a time almost latent. It is most common in the young, and towards the end of the disease. The expectorated matters may contain sugar. Gangrene of the lung, or a form of necrosis of the lung-tissues, has been noticed. With this form of gangrene the sputum may be odourless.

*Skin.*—The skin is usually dry and scurfy, often extremely itchy; wounds inflicted by scratching heal with difficulty. Copious saccharine sweat is observed in a certain number of instances. There is a marked tendency to the formation of boils and carbuncles. Boils often occur early in the disease, and may give the clue to the existence of diabetes. Carbuncles occurring late in the disease may be the immediate cause of death.

*Nervous System and Special Senses.*—The sight is often affected in diabetes, most frequently by the formation of diabetic cataract. Operations in such cases do badly till the disease is cured, and are seldom tried, for the cataract occurs late in the disease, and advances rapidly. A form of retinitis not unlike that of albuminuria is sometimes found. Other forms of imperfect vision of uncertain origin occur in diabetes. They go by the general term of diabetic amblyopia.

Along with the physical, the mental powers fail, and the moral sentiments become blunted, which, to the friends of the patient, is not the least distressing feature of the malady.

*Genital Organs.*—Early in the history of the disease, all sexual appetite disappears, and sexual power soon fails in the male—but with improvement this may return. In the advanced stages amenorrhœa is not unusual amongst females.

**COMPLICATIONS.**—Several of the symptoms just described are regarded by some authorities as complications of diabetes rather than as belonging essentially to the disease. Such are especially diabetic cataract and amblyopia, boils and carbuncles, and the chronic pneumonia or phthisis in which diabetes so frequently ends.

Amongst the intercurrent diseases that are specially to be watched for and seriously regarded, one of the most important is albuminuria, the appearance of which may encourage a false prognosis, from the fall in specific gravity of the urine that attends it.

*Diabetic Coma.*—This is a not infrequent terminal symptom of diabetes. It is more liable to occur in the early stages of severe cases in young persons. It is especially noted after muscular exertion, and after the first adoption of an anti-diabetic diet. Constipation predisposes to its development. Cases of diabetic coma are divided into three groups. In the first group the attack begins with headache or epigastric pain and nausea, followed

by a great feeling of anxiety, or by restlessness and perhaps delirium, after which a peculiar dyspnoea sets in. The dyspnoea affects both inspiration and expiration, and no physical cause can be found for it on examination of the chest, and there is usually no cyanosis. Comatose symptoms then come on, which gradually deepen. The pulse is much quickened, and the temperature is abnormal. The coma generally ends fatally within forty-eight hours, and only a few cases have been known to recover. The symptoms of the second group closely resemble those of renal uræmia. The dyspnoea is not so well marked as in the preceding form. The patient complains of general weakness, becomes drowsy, lapses into a state of coma with low temperature and small pulse, and soon dies. The third form exhibits all the symptoms of acute alcoholic intoxication. The patient does not show the same muscular weakness as is observed in the two preceding forms. He is attacked suddenly by great excitement, staggering gait, and drunken delirium. Gradually drowsiness and coma develop as in the other forms, and death ensues. In all these forms, and during and preceding the attack, a peculiar sweet smell, resembling chloroform, is perceived in the breath. The urine has a similar odour; and it gives the so-called 'acetone reaction' with perchloride of iron—that is, when a solution of perchloride of iron is added in excess a deep red port-wine colour is produced.

The pathology of diabetic coma has been much debated. Kussmaul believed that the symptoms were due to the presence of acetone in the blood; but it has been shown that other substances besides acetone give the peculiar reaction with perchloride of iron. The blood of diabetics has been often observed to contain excessive quantities of fat. Drs. Sanders and Hamilton described a case of diabetic coma, in which much fat was found in the blood, and numerous fat-emboli were seen in the pulmonary capillaries; and they suggested that fat-emboli in the lungs and brain were the cause of the symptoms. Similar cases have been described by others. Drs. Dreschfeld and Taylor, however, were unable to find fat-emboli in seven cases examined by them, although the blood was exceedingly rich in fat.

**DIAGNOSIS.**—The diagnosis of diabetes depends on the discovery of sugar, in notable quantity, in the urine of the patient. But before the investigation for sugar is undertaken, there have usually been observed by the patient some of the early indications of diabetes, of which the following are the most frequent, though no one definite symptom invariably heralds the disease: (1) dryness of the mouth and thirst; (2) bodily weakness and gradual emaciation; (3) dryness of skin, with itching and a tendency to successive crops of boils; (4) urination in increased quantity, the urine being of a greenish-yellow tint, with the odour

described; (5) defects of vision. Occasionally the attention of the patient is drawn to the state of his urine by the attraction it presents to ants, flies, and other insects; or by the formation of white spots of sugar on his dress and boots left by the urine on evaporation.

We must not forget that in true diabetes we find sugar in notable quantity. There are often present in the urine other reducing agents (such as uric acid and colouring matters), so that the amount of sugar detected must be such as to admit of no doubt whatever. Again, the presence of the sugar must be persistent, hence a single examination will not suffice for diagnosis unless sugar be found in large quantity. It may so happen that the patient when seen is not passing sugar, from the influence of restricted diet, or from some other cause, such as pneumonia or other feverish condition. It is then best to examine the urine passed an hour or two after a meal, or even to permit the use of starchy food for a day or two, so that the constitutional proclivities of the patient may be the better ascertained. To determine the existence of sugar is not enough: it is always necessary to determine the quantity passed, so as to obtain a clue to the intensity of the disease, and to judge of the effects of treatment.

**Qualitative Testing for Sugar.**—The presence of sugar in the urine may be detected in various ways. When saccharine urine is mixed with yeast and kept in a warm place, it speedily ferments, with production of alcohol and evolution of carbonic acid; and as no other substance is capable of undergoing this transformation, the occurrence of fermentation with yeast is certain proof of the presence of sugar. The signs of fermentation are evolution of carbonic acid and the lowering of the specific gravity. By the latter of these two signs considerably less than one per cent. of sugar can be detected in the urine. The method of carrying out this test is fully described under the head of quantitative testing.

**Moore's or Heller's test.**—When saccharine urine is boiled with liquor potassæ the sugar is decomposed, and a compound is formed, giving its colour, black or brown, to the fluid. A convenient test-tube is filled one-third full with the urine, and an equal quantity of liquor potassæ is added. The two should then be well mixed by shaking, and the heat of a spirit-lamp applied to the upper portion of the mixed fluids. If sugar be present this portion will gradually darken, the tint assumed varying in depth according to the quantity of sugar present. This test is very convenient, but it is liable to several objections, notably these:—(a) It is far from delicate, requiring as much as three parts in a thousand, or a grain and a half of sugar to the ounce, to afford any satisfactory indication. (b) It is practically useless for quantitative purposes, though the plan has been

tried of comparing the colour produced with the colours of solutions containing known quantities of sugar, as is done in the Nessler process for substances producing ammonia and its allies. (c) It is liable to two notable fallacies. (1) High-coloured urine is always darkened in tint, sometimes blackened, by boiling with liquor potassæ. (2) Liquor potassæ very often contains lead, which is liable to be converted into black sulphide when boiled with caustic potash, if albumen or any organic matter be present in the urine. The former of these risks cannot well be obviated; the latter may, by first testing the purity of the liquor potassæ, and keeping it in green glass instead of white glass bottles.

**Indigo-carmin test.**—If a solution of indigo-carmin be rendered alkaline by carbonate of sodium, and boiled with a small quantity of grape-sugar, the indigo-blue becomes reduced to indigo-white, and causes the blue solution to assume a yellow colour. This test, originally introduced by Mulder, has been recommended by Dr. George Oliver, who makes use of it in the convenient form of test-papers. Two test-papers, one saturated with indigo-carmin, and the other with carbonate of sodium, are digested in a small quantity of water, the result being a clear blue solution. To this one drop of the suspected urine is added, and the mixtures boiled; if sugar be present the blue colour will successively give place to reddish-violet, different shades of red, and finally to a pale yellow tint. On standing, the solution re-absorbs oxygen from the air, and gradually returns to its original blue.

**Picric acid test.**—This test was introduced by Dr. George Johnson. The principle of the method depends on the power of grape-sugar to change a yellow solution of picric acid, in the presence of caustic potash, to a red solution of picramic acid—and the depth of the red colour varies with the amount of sugar present. Dr. Johnson has also applied this method for quantitative determination. The test is, however, less delicate than that of Fehling, to be presently described.

**Trommer's test.**—Equal volumes of the suspected urine and liquor potassæ are mixed together in a test-tube with a few drops of a 10 per cent. solution of sulphate of copper. Heat is then applied; and, if sugar be present, when the boiling-point is reached an orange-coloured precipitate of suboxide of copper is produced. This mode of applying the copper-test is, however, far inferior to the following.

**Fehling's test or method.**—This testing fluid may be procured ready-made, but the following is the formula for it, as slightly modified by Dr. Pavy, and fitted for daily use:—Five grains of sulphate of copper, ten grains of neutral tartrate of potassium, and two drachms of liquor potassæ. A more exact

formula will be given farther on. The fluid thus formed is of an intense blue colour, clear and bright. When the test-fluid is to be used, a small quantity of it should first be raised to the boiling-point, because by prolonged keeping the tartaric acid undergoes change, a substance being formed from it which is capable of reducing copper, and might give rise to confusion. But if on boiling the test-fluid no copper is thrown down, the suspected urine should be added drop by drop, the mixed fluid being at the boiling-point. If sugar be present in quantity, it will throw down the copper in the form of a red or orange precipitate. The quantity of urine added must never exceed the bulk of the test-fluid, and the upper portion of the fluid should be heated, so as to contrast with the lower portion. Should suboxide of copper be thrown down when the test-fluid is boiled, the fluid must be filtered before adding the suspected urine, or, still better, a new fluid be prepared. To obviate as far as possible such inconveniences, the cupric and alkaline fluids should be kept in separate bottles until about to be used.

When the quantity of sugar in the urine is very small, as may occur in ordinary diabetes after long fasting or the use of a rigidly restricted diet, or during an access of fever, still more minute precautions must be taken. The most important of these is to use a great excess of the test. When the copper solution is added drop by drop to a healthy urine, at a boiling heat, the blue colour is immediately discharged, although not a particle of sugar be present, and the urine assumes a deep amber tint. The degree to which urines exercise this decolorising property over Fehling's test varies with their concentration. A dense urine (sugar free) will discharge the colour from nearly its own bulk of Fehling's standard solution; but even the most dilute urines have a considerable power this way. To avoid this fallacy, and secure an excess of the test, the most certain method is to heat the solution first, as already recommended, and to add the suspected urine afterwards—and never to add more, but always something less, than the bulk of the test-solution. The mixture is then again raised to the boiling-point. It then changes (if sugar be present) to an intense opaque yellowish-green, and slowly a bright yellow deposit subsides. If the urine contain less than half a grain per cent. the precipitation does not take place immediately, but occurs as the liquid cools—in five, ten, or twenty minutes—and the manner of the change is peculiar. First the mixture loses its transparency and passes from a clear olive-green to a milky opacity. This green milky appearance is quite characteristic of sugar. Some of the natural urinary ingredients have a certain power of reducing the oxide of copper to a state of suboxide, and of becoming thereby a source of fallacy in

using this test for the detection of sugar. But this fallacy is easily avoided by not prolonging the ebullition. The fluid should simply be raised to the boiling-point, and then allowed to slowly cool. If such a proceeding fail to yield an indication of sugar, no amount of boiling will develop a trustworthy reaction. An increased delicacy can be imparted to this method by the following process, first suggested by Seegen. The urine is repeatedly filtered through animal charcoal until it is completely colourless. A little pure water is then passed through the filter, and to this water the test is applied in the usual way. An exceedingly minute trace of sugar (0.01 per cent.) can be detected by this procedure.

**Quantitative Testing for Sugar.**—*Fehling's volumetric method.*—This method, now in common use, is founded on the fact that the proportion in which sugar reduces copper is constant. One equivalent of grape-sugar decomposes exactly ten of sulphate of copper, or 180 parts by weight of grape-sugar decompose 1246.8 parts by weight of sulphate of copper. This being borne in mind, and a copper solution of known strength being used, it is easy to determine the quantity of sugar in any given specimen of urine. The quantities may be calculated according to the metric system, or by grains and minims. If we adopt the metric system, our fluid will consist of the following ingredients:—

Sulphate of Copper (crystals) 40 grammes.  
Tartrate of Potassium (neutral) 160 grammes.

Liquor Sodæ (sp. gr. 1.12) 750 grammes.

Water to 1154.5 cubic centimetres.

These should be carefully mixed; or, what is better, the copper and alkaline solutions are made separately, so that five cubic centimetres of each, or ten of the mixed fluids, will exactly decompose .05 gramme or 50 milligrammes of sugar.

According to the English system of measurement, Dr. Pavy's solution is the most convenient. It consists of sulphate of copper, 320 grains, dissolved in ten ounces of distilled water; and tartrate of potassium (neutral), 640 grains, with caustic potash 1280 grains, also dissolved in ten ounces of distilled water. These fluids may be kept separate or mixed. In mixing, the copper should be added to the alkaline solution, not *vice versa*, to prevent the formation of any precipitate. One hundred minims of this mixed fluid are decomposed by half a grain of sugar. Only a minim measure and a porcelain capsule, or other vessel which will stand heat, are required for Dr. Pavy's solution in the procedure, which is as follows: Most specimens of diabetic urine, containing too much sugar for accurate testing, first require dilution with water; and the most convenient degree of dilution is when one-tenth of the fluid is urine. Next put ten cubic centimetres of the metric copper solution, or one hundred minims of Pavy's

solution, carefully measured, in a small porcelain capsule. The fluid being deep blue is better for dilution, so as to diminish the intensity of tint. Of course this does not alter the quantity of copper present in it. The porcelain capsule with its contents is to be placed on an iron retort-stand, at such a level that the flame of a spirit-lamp will easily play on the capsule. Meanwhile a pipette, graduated from above downwards, either in minims or cubic centimetres, is filled up exactly to the 0 in the graduated scale with the diluted urine. When the solution of copper is boiling, the urine is added to it from the pipette, drop by drop, stirring carefully the while, until signs are shown of a decoloration of the cupric solution. The moment all the copper has been thrown down as suboxide, and all shade of blue or green has disappeared, the addition of the diluted urine is stopped, and the quantity already used read off on the graduated pipette. To ascertain the quantity of sugar in the urine is now a simple calculation. We know how much urine has been employed in reducing the 10 cubic centimetres, or the 100 minims, of the cupric fluid, but these measures represent exactly 50 milligrammes and half a grain of sugar respectively. The quantity contained in the diluted urine being hence deduced, multiply this by ten, to get the quantity contained in the urine as passed. Next multiply by the total quantity of urine passed in twenty-four hours, to ascertain the full amount of sugar passed in this period. In all such analyses the sample examined should be taken from the mixed urine passed during the whole twenty-four hours. That passed after prolonged fasting is the richest, that passed three or four hours after a meal the poorest, in sugar.

*Roberts's fermentation method.*—We have already noticed the fermentation method for demonstrating the existence of sugar in urine. Sir William Roberts has also devised from it a highly accurate quantitative process. It is as follows:—

Put about four ounces of the suspected urine into a clean eight- or twelve-ounce glass bottle. Introduce a piece of dry German yeast, about the size of a cob-nut, but divided into small pieces. Cork the bottle with a grooved cork to allow the escape of gas. Fill a companion bottle *quite full* with the urine. Cork quite tightly, and set the two side by side for twenty-four hours in a warm place—the mantelpiece will do. By the end of that time fermentation will probably have ceased, and the yeast fallen to the bottom. The specific gravity of the two specimens must now be carefully taken with an accurate urinometer, that of the unfermented bottle being taken as the standard. The fermented urine will have lost density from two causes: First, the sugar which gave the increased specific gravity has been destroyed; and, second, in its place have been formed alcohol, which is lighter

than water, and carbonic acid, which has escaped. *Every degree of specific gravity thus lost represents a grain of sugar in the ounce of urine.* Thus, if there is a loss of twenty-five degrees of specific gravity, the urine would contain twenty-five grains of sugar in each ounce. Multiply this by the total number of ounces passed, to get the amount of sugar discharged *per diem*. This plan is especially useful for noting the quantity of sugar passed day by day, and can be easily undertaken by the patient or his friends.

*Estimation by the polariscope.*—A plan of estimating sugar employed a good deal abroad depends upon the power of diabetetic sugar to turn the plane of polarisation to the right. The degree of rotation is in proportion to the quantity of sugar contained in the urine. The apparatus used commonly goes by the name of the Ventske-Soleil apparatus, from its inventors. It is best adapted for light-coloured urines. If the urine be deep in colour it requires to be diluted.

**PROGNOSIS, COURSE, AND TERMINATIONS.**—The prognosis of confirmed diabetes is ever unfavourable. Amelioration is common, but a perfect cure, save in exceptional cases, is rare. Diabetes coming on suddenly and from special causes, such as injury to the head, is more likely to do well than when more gradually developed. The younger the patient, the more sugar passed, the greater the emaciation and debility, the worse is the prognosis. Diabetes persistent with pure flesh diet is worse than if persistent only with a free starchy or saccharine diet. Loss of appetite and of digestive power, as indicated by the condition of the fæces, is of evil omen. When albumen appears in the urine in the course of diabetes, the specific gravity of the fluid diminishes, often giving rise to a false impression to the effect that, as the specific gravity has decreased, the diabetetic state must be improved. The only true test of recovery is the power of consuming ordinary mixed food with impunity; but Seegen says that out of two hundred cases he had never seen this result. But by rigid or limited dieting, the patient may live, and even enjoy life, for many years. Heredity, directly or collaterally, adds to the darkness of the outlook. Cases resulting from injury to the brain or other parts of the nervous system are often the most hopeful with which we have to deal, though by no means always so.

The course of diabetes is on the whole chronic. Most frequently it develops gradually, though in some cases suddenly; and it generally lasts from six months to three or four years. In stout elderly persons it may exist much longer, especially with good digestion and a limited dietary. On the other hand, Sir William Roberts records a case which proved fatal, after a well-marked onset, in eight days—the shortest period known to the writer. Another case was fatal in three weeks,

the patient being three years old. Some cases are recorded of death at still earlier periods, but these were most probably cases of long duration in an unnoticed shape suddenly developed into an aggravated form. A fatal termination of diabetes may be brought about, as already indicated, in various ways. One is by diabetic coma, not unlike the first stages of uræmia. In the advanced stages of diabetes, the strength being very low, comparatively slight causes may produce fatal effects.

**TREATMENT.**—Though we are ignorant on many points as regards diabetes, yet when we come to its treatment, we have these undoubted facts—that sugar cannot be formed out of nothing; and that the series of substances out of which it may be formed is limited. And though we cannot absolutely succeed in feeding the patient on substances which will not yield sugar, we can supply a nourishing diet furnishing sugar-forming materials in the scantiest proportion—an end best attained by a pure meat diet. But besides dietetic measures, other, though subsidiary, means may be taken to limit the formation of sugar by suitable hygienic and medicinal treatment. It is convenient to treat of these separately, though they should be employed in conjunction.

*Dietetic treatment.*—All authorities agree that meat should be the main constituent of the patient's food, and that starch, and cane and grape sugar, should be avoided, as well as the substances containing them. It is very important in constructing a diet scale to give the patient as much variety of form as possible, the basis remaining the same. As the diet of the patient is the main factor in his treatment, it is worth the practitioner's while to study the various changes and combinations of food which may be given with impunity. As regards vegetables, the rule is that all green vegetables, or the green parts of vegetables, may be eaten; for where chlorophyll is abundant, starch and sugar are commonly scanty; but this rule has important exceptions, which will readily occur to the reader. Thus the green parts of asparagus and celery may be used, whilst the white portion is highly saccharine. Globe artichokes may be used; Jerusalem artichokes are objectionable. Cabbage, endive, spinach, broccoli, Brussels sprouts, lettuce, spring onions, water-cress, mustard and garden cress, and celery may be used freely. Most fruits are forbidden, but nuts may be used if they can be digested. French beans may be used when quite green; when older the beans themselves must be removed. Haricot beans, peas, and all cereals; tapioca, sago, arrowroot, all forms of macaroni, potatoes, carrots, turnips, parsnips, and beetroot are in the forbidden list. Cheese, especially of the poorer kinds, may be used. Cream, butter, and other fatty articles may be used freely. To sweeten tea or coffee, gluside has been

suggested; but both will soon be found more refreshing without any sweetness. Cocoa made from the nibs can be used. Small quantities of cold tea without milk or sugar, with slices of lemon in it, will often be found palatable, cleansing the mouth and relieving thirst. Rinsing the mouth with iced water will often give more relief than a hearty draught. Slowly sucking ice is a very good plan for relieving thirst. All sweet drinks are in the forbidden list, including most sherries and ports, though some of the former may be found nearly sugar-free. Nearly all brandies contain sugar. Light French and German wines contain little or no sugar. Gingerbeer and lemonade are very objectionable; so are champagne, sweet beer, cider, porter and stout, rum and gin. Whisky is probably the best form of spirit. The use of alcohol in these cases has been gravely questioned. Where alcohol has not been used before the onset of the disease, the patient is probably better without it; but it is quite clear that in many cases it may be taken in moderation with advantage.

There is difficulty in procuring a substitute for bread and potatoes. Three imperfect substitutes are employed—namely, gluten bread, bran bread, and almond bread. Gluten bread, as introduced by Bouchardat, consists of flour out of which nearly, but not quite, all the starch has been washed. It is tough, and patients tire of it; better forms of gluten bread may be easily obtained in London. This last is palatable and nearly starch-free, but does not keep well. Bran bread is now often made, in the form of biscuits or cakes; the bran should always be washed nearly free of flour. Bran bread is hardly admissible when there is a tendency to diarrhœa, but may be useful in constipation. Almond cakes were first introduced by Dr. Pavy. They are rather rich to be eaten with meat, but used by themselves or with wine are excellent. Almond flour may now be obtained from which much of the oil has been expressed.

We pass over Dr. Donkin's skim-milk treatment of diabetes with the remark that in the hands of Dr. Donkin and some others the method has been successful; in the hands of many eminent physicians, both at home and abroad, it has done unmitigated harm. Probably the explanation of any successful cases may be found in the fact, that in certain conditions of diabetes, milk-sugar, as well as certain other substances, does not give rise to grape-sugar. If milk is to be used, butter-milk or sour milk will be best. The treatment by sugar or glycerine is self-condemned.

*Hygienic treatment.*—In this the first and most important point is regular exercise, especially riding or walking, short of fatigue. Bouchardat has strongly advocated gymnastic exercises. These would be useful in modera-

tion, especially in bad weather. Nothing is more grateful or beneficial to the skin after such exercise, or even without it, than a warm bath, temp. 80° to 90°, with a little common washing soda in it. In all cases the avoidance of wet and cold is important. Flannels, frequently changed, should be worn; and it is always safer to change the clothes after the slightest exposure to damp. Little may suffice to give rise to a fatal pneumonia.

*Medicinal treatment.*—This must be considered as subsidiary to dieting, but there are many cases where undoubted benefit results from drugs. Of those which have been found of real value, the foremost is opium. Yet there is no unanimity of opinion as to the mode in which opium acts, and its apparent effects are most discordant—in some cases reducing both sugar and urine without sleepiness, in others speedily giving rise to drowsiness and even apparently to coma. The varied susceptibility of different patients to this drug is very striking. Some will take 20 or even 50 or 60 grains a day with no apparent physiological effect beyond slight contraction of the pupil; others again cannot endure even a few grains. The writer's experience is decidedly in favour of opium. Morphine answers well in some cases. Codeine has been strongly recommended by Dr. Pavy as being the influential ingredient in the raw opium. He begins with doses of half a grain. Next to opium come alkalis, and especially some alkaline waters. Alkalis themselves may be given in various forms—as cream of tartar to relieve thirst, as citrate or bicarbonate of potassium, or, if there is a tendency to gastro-intestinal catarrh, as liquor potassæ, with or without a bitter. The waters in most repute in diabetes are those of Carlsbad, Vichy, Vals, Bethesda, and Contrexeville. An annual visit to Carlsbad, with the rigid system of regimen and dietary carried out under the resident physicians, often suffices, with due care, to keep the patient fairly well for many years.

Lactic acid has been strongly advocated by Cantani. His results seem good, but he also makes use of a most rigid dietary. Pepsin and rennet have been used, but without real advantage.

Of secondary remedial agents, the three most important are strychnine, iron, and cod-liver oil; these favour nutrition, and the cod-liver oil seems to improve the temperature somewhat. Laxatives, not purgatives, should be used for the troublesome costiveness. Mineral waters, castor oil, or alkaline purgatives suit best. Phosphorus in combination with iron as hypophosphite, taken in pills, has proved useful.

**MANAGEMENT OF A CASE OF DIABETES.**—By way of recapitulation we may say a few words here on the management of a case of diabetes. When a case comes under the care of the practitioner he must first ascertain the general state of the patient as a basis

for future comparison. The patient's weight must be carefully taken, and the state of his bowels noted. The quantity and characters of urine passed should be noted daily for a short time, the patient still consuming ordinary diet, unless there be some urgent reason to the contrary. After a day or two the restricted diet should be gradually commenced, sugar and potatoes being first cut off. Next the bread should go, being first of all cut down and used toasted hard or torrefied, and this should merge into the use of bran cakes or gluten bread. Above all things, the patient must not be disgusted with his food, for this favours the secret consumption of forbidden dainties. Week by week the weight should be taken; day by day the sugar estimated, as may easily be done by Roberts's method, and the whole arranged on a card so as to be seen at a glance. Warm baths, exercise, and the other adjuvants must be assiduously employed; and as soon as the effects of the limited diet are clearly marked, opium may be tried, if required. If well borne it should be used determinedly, and pushed to its physiological effects, as indicated by the contracted pupil. If the patient is seen daily, his diet should be regulated each day; if only at intervals, certain available changes should be indicated. When convalescence begins, and the urine has for some time been free from sugar, the diet may be gradually relaxed, beginning with substances containing little starch or sugar, gradually extending to bread in small quantity; potatoes should come last: sugar itself never. When, with every care, restriction of diet effects no diminution of sugar, or, if that be limited, emaciation and weakness rapidly go on, it will be a question whether it may not be best, as it often is, to return to a practically unrestricted diet.

ALEXANDER SILVER.

**DIAGNOSIS of Disease.**—See DISEASE, Diagnosis of.

**DIAPHORESIS** (διά, through; and φερέω, I convey).—The act of perspiring. The term is more generally applied to perspiration artificially induced.

**DIAPHORETICS** (διά, through; and φερέω, I convey).

**DEFINITION.**—Remedies which increase the secretion of sweat. When the increase is so great as to cause the perspiration to stand in beads upon the surface, they are usually termed *sudorifics*.

**ENUMERATION.**—The principal diaphoretic measures are—The Vapour Bath, Turkish Bath, and Wet Pack; Warm Drinks; Warm Clothing; Jaborandi, Pilocarpine; preparations of Antimony; Ipecacuanha; Opium and Morphine with their preparations; Sarsaparilla, Guaiacum, Serpentry, Sassafras, Senega, Mezereon, Camphor; Sulphur; Ammonia and its Carbonate, Acetate, and

Citrate; Alcohol; Ethers (especially Nitrous Ether); and Chloroform.

**ACTION.**—The secretion of sweat usually consists of two parts, namely, a free supply of blood to the sweat-glands, and the abstraction from it of the materials for sweat by the cells of the gland. These two processes sometimes occur independently of each other. In fevers the supply of blood to the glands is abundant, but they do not secrete; and a similar condition is observed in belladonna-poisoning. Belladonna and atropine possess the power of paralysing the secreting nerves of the sweat-glands, just as they do those of the salivary glands, and thus the skin remains dry, although the cutaneous vessels are much dilated. In collapse the cutaneous glands secrete a cold sweat profusely, although the supply of blood to them is deficient.

The secreting cells appear to be under the influence of nerves, by exciting which secretion occurs. The centres for the secreting nerves of the sweat-glands appear to be situated in the spinal cord, and in the medulla oblongata. The fibres seem to run in the same path as the vaso-motor nerves. The secretory nerves of the sweat-glands may be excited directly by stimulation of the nervous trunks in which they run; and the sweat-centres may also be reflexly excited by irritation of various sensory nerves. Certain substances, such as nicotine and carbonic acid, seem to stimulate the sweat-centres; whilst other drugs, such as pilocarpine, appear to act upon the peripheral terminations of the secretory nerves in the sweat-glands themselves. Several remedies, at the same time that they excite secretion, likewise increase the flow of blood through the skin, rendering it redder, warmer, and more vascular. Others, again, excite the secretion at the same time that they diminish the cutaneous circulation. Diaphoretics have therefore been divided into two classes, the former kind being termed *stimulant*, and the latter *sedative* diaphoretics. The exact mode in which each drug already enumerated produces diaphoresis has not yet been ascertained; but antimony, ipecacuanha, and jaborandi are classed as sedative diaphoretics, and all the others as stimulating ones. The supply of blood and the secretion are both increased by the application of warmth, by the ingestion of warm fluids, and by the action of jaborandi.

**USES.**—Diaphoretics are employed to increase the flow of blood to the surface, and possibly to aid the elimination of excrementitious products in internal congestion, such as catarrh of the respiratory passages or digestive tract, and in febrile conditions generally. In fevers, the cutaneous circulation is generally active, and the so-called sedative diaphoretics are then most useful. Diaphoretics are also used to increase the

elimination of water by the skin, and thus lessen the accumulation of fluid in dropsy, or to relieve other excreting organs, such as the kidneys in albuminuria and diabetes insipidus, or the intestines in diarrhoea. In these cases stimulant diaphoretics are indicated.

T. LAUDER BRUNTON.

### DIAPHRAGM, Diseases of the.

The diaphragm is an important part of the respiratory apparatus, in relation to the movements of breathing, and by no means receives the attention from a pathological and clinical point of view which it deserves. Only a brief outline of its affections can be given within the limits of the present article; and for practical purposes they may be conveniently discussed according to the following arrangement:—

1. PHYSICAL INTERFERENCE WITH THE DIAPHRAGM, AND DISPLACEMENT.

2. FUNCTIONAL DISORDERS. (a) Paralysis. (b) Spasm.

3. ORGANIC LESIONS. (a) Injury, Perforation, and Rupture—Diaphragmatic Hernia. (b) Inflammation, acute or chronic. (c) Muscular Rheumatism. (d) Atrophy and Degeneration. (e) Morbid Formations.

1. PHYSICAL INTERFERENCE WITH THE DIAPHRAGM, AND DISPLACEMENT.—The diaphragm is frequently interfered with by morbid conditions within the chest or abdomen, which impede its movements, displace it more or less, either upwards or downwards, or render it tense and stretched. The entire structure may be thus affected, or only a portion of it, such as one lateral half or its central part. The chief thoracic conditions by which the diaphragm may be thus affected are pleuritic effusion, empyema, or pneumothorax, emphysema of the lungs, abundant pericardial effusion, enlargements of the heart, and tumours within the chest. Chronic contracting affections of the lung and pleura tend to draw it upwards, by a process of suction. Pleuritic adhesions, considered independently, have rather a depressing influence than otherwise (Walshe). The principal abdominal conditions which may raise the diaphragm are a distended stomach, tympanites, ascites, peritonitis, pregnancy, large faecal accumulations, and tumours or enlarged organs which attain considerable dimensions, especially ovarian, hepatic, splenic, or renal tumours. It sometimes happens that the diaphragm is interfered with both from its thoracic and its abdominal aspects. Tight lacing may materially embarrass and alter the position of this structure.

**SYMPTOMS.**—The symptoms induced by this mechanical interference are readily explained by its effects. A sense of uneasiness and discomfort is often experienced around the lower part of the chest, amounting sometimes to considerable tension or tightness.

There is not any actual pain, but in some instances, where the diaphragm is much pushed down, the patient complains of a painful sensation referred to the ensiform cartilage, as if the attachment of the diaphragm at this point were being severely dragged upon. The act of respiration is more or less impeded, and this often seems to be the cause of the discomfort experienced. A sensation frequently complained of by patients is that they cannot take a full breath. Respiration may be much hurried, or oppressed and laboured; and not uncommonly the normal relation between the thoracic and abdominal movements is markedly altered, as observed on inspection and palpation, and the diaphragm may so act as to draw in the lower part of the chest-walls in inspiration. Occasionally a kind of spasmodic cough seems to be excited by the tension of the diaphragm produced by certain conditions. The act of coughing is also frequently rendered more or less difficult and ineffectual.

The actual position of the different parts of the diaphragm in a particular case can only be determined by carefully noting the physical signs afforded by the structures in contact with it, on its thoracic and abdominal aspects respectively.

2. **FUNCTIONAL DISORDERS.**—The affections of the diaphragm included within this group are (*a*) **Paralysis**; and (*b*) **Spasm**. It will be understood that in the cases now under consideration there is no structural change in the diaphragm itself.

*a. Paralysis.*—The diaphragm is completely paralysed when the spinal cord is destroyed at the origin of the phrenic nerve, whether as the result of injury or disease. If one or both phrenic nerves be cut across, destroyed by disease, or even severely compressed, the same effect will be produced, either one lateral half or the whole of the diaphragm being paralysed, according as one or both nerves are involved. This structure may also be implicated in diphtheritic paralysis; lead-palsy; and hysteria. Diaphragmatic paralysis has also been attributed to cold. *See PHRENIC NERVE, Diseases of.*

**SYMPTOMS.**—Where paralysis of the whole diaphragm is suddenly produced, death speedily ensues from the grave impediment to the respiratory function resulting therefrom. If it is brought about gradually, or if only part of the structure is involved, the effects are seen in more or less interference with this function, and with the acts in which respiration is concerned. Thus there will be a subjective sensation of a want of power to breathe; while the respiratory movements may be hurried and shallow. It has been noted, however, that, when the patient is at rest, breathing is often quite easy, but any exertion causes it at once to become frequent, and brings the extraordinary muscles of respiration into play. Physical examination

shows that, if a deep inspiration be taken, the epigastrium and hypochondria sink in instead of protruding, while during expiration these regions bulge out again. If only one half of the diaphragm is affected, this abnormal movement is unilateral. Coughing and sneezing cannot be performed efficiently, and sputa cannot be easily expelled; while the abdominal acts for which a tense diaphragm is required, such as defæcation or vomiting, are also ineffectual or impracticable. A peculiar dysphonia has been described, in which the voice loses its power as the day advances, becoming at last a mere cracked whisper. The lower parts of the lungs tend to be more or less collapsed and congested; and if bronchitis sets in, the patient is in grave danger.

*b. Spasm.*—The diaphragm may be the seat either of clonic or tonic spasm or cramp. The disorder may depend upon disease of the nerve-centre at the origin of the phrenic nerves; irritation of these nerves in their course; direct excitation of the diaphragm; or reflex causes. Tonic spasm is most strikingly observed in cases of tetanus; of poisoning by strychnine; or of hydrophobia. A form of asthmatic attack has also been attributed to this condition of the diaphragm; and it may result from immoderate laughter.

**SYMPTOMS.**—The symptoms will vary in different cases. Tonic contraction of the diaphragm gives rise to severe pain, and a sense of constriction in the corresponding region, which may come on in paroxysms; clonic spasms also originate painful sensations after a time, which may become very considerable. Hiccough is probably due mainly to a clonic spasm of the diaphragm (*see HICCOUGH*). If this structure should become rigidly fixed, respiration is gravely interfered with, and the patient soon presents the phenomena of apnoea, which will end fatally if the spasm is not relieved. In the form of asthma supposed to be due to diaphragmatic spasm, expiration is very difficult and greatly prolonged, inspiration being short and abrupt; the lungs are distended; great distress is felt; and there may be signs of impending death from suffocation. A spasmodic cough may be due to clonic spasm of the diaphragm.

3. **ORGANIC LESIONS.**—These may be briefly considered in the order in which they were enumerated at the commencement of this article.

*a. Injury, Perforation, and Rupture — Diaphragmatic Hernia.*—The diaphragm may be perforated, lacerated, or ruptured in connexion with various forms of injury, such as crushing accidents, fractured ribs, penetrating wounds, or gunshot injuries. Should the patient recover, a permanent opening may be left. Rupture of the diaphragm may also occur from violent strain, as of persistent retching, or during parturition; and from the effort to conceal or

suppress the cries of pain in parturition. In medical practice perforation of this structure may be met with as a congenital condition; as the result of the bursting of some fluid-collection through it, such as an empyema, pulmonary abscess, a sub-diaphragmatic, hepatic, renal, or other abscess, or a hydatid-cyst; or from its destruction in the progress of some organic lesion, such as malignant disease, an aneurysm, or a chronic gastric ulcer. It may occasionally occur independently of these causes, owing to the yielding of a weak portion of the diaphragm, especially between the attachment to the ensiform cartilage and the seventh rib. Congenital perforation is rare, but a considerable portion of the diaphragm may be thus deficient. The size and other characters of the perforation differ much in different cases. If it is produced by the opening through the diaphragm of a fluid-accumulation, this fluid escapes from the abdominal into the thoracic cavity, or *vice versâ*, the latter being exceptional; in other instances portions of the thoracic or abdominal organs pass through the perforation, constituting forms of *diaphragmatic hernia*. The writer had the opportunity of observing a remarkable instance in which the entire stomach had passed through an opening in the diaphragm into the cavity of the chest. In a case reported by Dr. Little, of Dublin, the diaphragm presented an almost circular opening, well-defined, sharp, with somewhat thick edges, and through this opening passed a hernia consisting of peritoneum containing some omentum, and about fifteen inches of the transverse and descending colon. The stomach and colon most frequently pass through the diaphragm. In rare instances the small intestines, spleen, or other structure form part of the hernia.

**SYMPTOMS.**—To recognise clinically a perforation or rupture of the diaphragm is generally no easy matter. In cases of sudden and extensive rupture, there will probably be grave collapse and speedy death, and the patient may present marked risus sardonius. Often there are no symptoms referable to the diaphragm, though there may be signs indicating that its functions are more or less impeded. The occurrence of sudden perforation may be known from the previous existence of some condition likely to cause this event, such as empyema, or an abdominal abscess; the supervention of acute pain, accompanied with indications of shock or collapse, and the disappearance or modification of the signs of the original morbid condition; followed by the development of phenomena revealing that fluid has passed through the diaphragm, and accumulated in the thoracic or abdominal cavity, as the case may be, or that some secondary affection has been set up as the result of the perforation, such as peritonitis or pleurisy. A fluid collection may, however,

penetrate the diaphragm without giving rise to any very evident disturbance. When an organ passes through this structure, the symptoms present, if any, are more likely to be associated with this organ than with the diaphragm, and physical examination may possibly detect the displacement. In the case of hernia of the stomach already referred to, the chief symptom was urgent vomiting, which occurred immediately after taking any food or drink.

**b. Inflammation—Diaphragmitis.**—The serous covering of the diaphragm, either on its thoracic or abdominal aspect, is not uncommonly involved in cases of acute pleurisy or peritonitis respectively, and the inflammatory process may penetrate its structure. It may also be involved by extension from pericarditis. Inflammation of the substance of the diaphragm may further arise from injury, direct irritation, pyæmia, or without any evident cause. The anatomical conditions observed are increased vascularity and sometimes ecchymosis; the formation of lymph upon its surfaces, or exudation into its substance; softening and degeneration of its muscular tissue or central tendon; or, in rare instances, suppuration, an abscess forming in the substance of the diaphragm, or pus collecting under one or other of its serous coverings. Ulceration and gangrene have been noticed in exceptional instances. Chronic inflammation of the diaphragm may occur, leading to a fibroid change in its muscular portions, either by extension from neighbouring structures, or as the result of chronic local irritation.

**SYMPTOMS.**—The symptoms of acute inflammation of the diaphragm are generally very obscure and ill-defined. The condition may be indicated by severe pain in the region of this structure, of burning and constrictive character, obviously increased by breathing, so that the respiration becomes instinctively thoracic, as well as hurried and shallow; and also much aggravated by coughing, defæcation, or any other act which disturbs the diaphragm, as well as by movements of the trunk, and pressure over the epigastrium. Sighing, hiccough, painful dysphagia, risus sardonius, and violent delirium are other symptoms described. The movements of respiration will indicate more or less complete paralysis of the diaphragm. The patient will probably be much distressed. More or less pyrexia will be observed. If an abscess should form, this might burst either into the chest or abdomen, and thus lead to secondary pleurisy or peritonitis. The inflammation might also spread to the pericardium. Chronic inflammation and its consequences may possibly be suspected from a want of free movement in the diaphragm, associated with conditions likely to originate this change; but it could scarcely be recognised with any certainty.

c. **Muscular Rheumatism.**—The diaphragm may be involved in this complaint, whatever its nature may be; probably it is attended with structural changes in the tissues. The affection is characterised by pain referred to the diaphragm, which may be very acute when it is in any way brought into play. So long as it is kept at rest, there may be no discomfort, but deep breathing causes considerable pain, so that the respiration is carried on in a shallow manner, and may be entirely thoracic. Such acts as coughing or defæcation cause much pain and a sense of aching.

d. **Atrophy and Degeneration.**—The diaphragm may be involved in the course of progressive muscular atrophy; it may also be atrophied from causes which produce general wasting; or undergo senile atrophy and degeneration; or be similarly affected from local causes, such as interference with its blood-supply from vascular degeneration, want of action, or after chronic inflammation. Fatty and fibroid degeneration are the chief forms met with. Brawny induration has been noticed in scurvy. These conditions tend to give rise to more or less evident interference with the functions of the diaphragm, which in extreme cases would amount to their total cessation, diaphragmatic breathing being rendered impossible, the symptoms being then the same as when the diaphragm is paralysed. In cases of progressive muscular atrophy the fatal termination may arise from this cause. There would not be any pain, but uncomfortable sensations might arise from the impeded respiration.

e. **Morbid Formations.**—The diaphragm is occasionally the seat of malignant disease, being usually involved by extension from some neighbouring structure. Syphilitic and other non-malignant solid growths have in rare instances been found in it. Parasitic formations may also occur in it—namely, hydatids, cysticercus, and trichina spiralis. Tubercle is occasionally found in the diaphragm. Possibly malignant disease might be indicated by signs of impeded diaphragmatic movements, with localised pain, accompanying indications of cancer in other parts. The implication of the diaphragm in trichinosis may also be recognised in some instances by severe pains, spasmodic contractions, and serious interference with diaphragmatic respiration. In most cases, however, the presence of any morbid growth in connexion with the diaphragm cannot be diagnosed during life, and is only discovered at the *post-mortem* examination.

**TREATMENT.**—But little can be done in most cases in the way of direct treatment in connexion with affections of the diaphragm. One of the most obvious indications is to get rid, if possible, of any condition which is mechanically displacing it, or impeding its movements, and preventing it from perform-

ing its functions. In the next place, any disease of which the condition of the diaphragm is but a part must receive due attention, such as progressive muscular atrophy, centric nervous disease, diphtheritic paralysis, lead-poisoning, hysteria, or trichinosis. Collapse or shock due to a sudden diaphragmatic lesion must be treated on the usual principles. Painful affections might be relieved by local applications of dry heat, fomentations, support by a bandage, or anodynes; and if acute inflammation is suspected, a few leeches might be applied. Paralysis or spasm of the diaphragm may call for the employment of electrical treatment, applied through the phrenic nerve; and various remedies are found useful in hiccough. See PHRENIC NERVE, Diseases of; and HICCOUGH.

**DIARRHŒA** (*διάρρœα*, I flow away).—  
SYNON.: *Defluxio*; *Alvi Fluxus*; Purging; Fr. *Cours de Ventre*; *Dévoïement*; Ger. *Der Durchfall*; *Bauchfluss*; *Durchlauf*.

**DEFINITION.**—A frequent and profuse discharge of loose or of fluid alvine evacuations, without tenesmus, mainly due to increased peristalsis of the large intestine.

**ÆTIOLGY.**—The causes *predisposing* to diarrhœa are individual peculiarity; childhood—especially the period of first dentition; the climacteric period; and hereditary or acquired weakness of the digestive organs.—The *exciting* causes may be thus classified: 1. *Direct irritation of the intestines* by: (a) *Food* in excess, or of improper quality—for example, salted meat, shell-fish, sour unripe fruit and vegetables, diseased, decomposed, or imperfectly masticated; the products of faulty digestion prematurely passing the pylorus; imperfectly elaborated and fermenting chyme; impure water, such as that containing from 3 to 10 grains of putrescent animal matter per gallon (Parkes); or imperfectly fermented malt liquors. Acute diarrhœa, especially in hand-fed infants, is very frequently caused by fermentation of milk either previous to or after ingestion—the irritant effect being due either to undigested casein, to the products of acid or alkaline fermentation, or to the formation of poisonous ptomaines or the presence of bacteria. (b) *Purgative medicines and irritant poisons.* (c) *Bile*, excessive or acrid. (d) *Fæces*, retained. (e) *Entozoa*—lumbriçi, tæniæ, trichinæ, and *entophyta*—mycosis enteralis (Buhl and others). (f) The contents of a *ruptured abscess* or *hydatid-cyst*. (g) *Intestinal lesion*—such as tubercular or other ulceration.

2. *Defective hygiene*.—Diarrhœa may arise from the dwelling being damp, cold, dark, and unventilated; or from foul emanations from decaying organic, especially animal matter, sewage, or fœcal collections. 3. *Chills, climatic variations, &c.* Diarrhœa has been attributed to insufficient clothing; sudden exposure to cold and damp; chills, as from wet feet, and damp bed or clothing; and rapid variations of temperature, such as hot days and cold nights. 4. *Nervous disturbances*, for example, depressing emotions—fright, grief; neuralgia, hepatalgia (Trousseau), dentition, and other causes of reflex disorder. 5. *Defective absorption with augmented peristalsis* of the small intestines, so that the food is passed unaltered—*hæmorrhagic diarrhœa*. 6. *Symptomatic* in various morbid states, for instance, in passive congestion of the portal vein from disease of the liver, heart, or lungs; peritonitis, especially puerperal; organic disease of the intestines—ulceration (simple, stercoral, typhoid, tubercular, cancerous), lardaceous degeneration, enteritis, acute or chronic; cholera; typhoid fever; dysentery; occasionally in pyæmia, measles, scarlatina, confluent small-pox, malaria, gout, Bright's disease (its later stages), and in anæmia and exhaustion, as from over-lactation, phthisis, cancer, Addison's disease, Hodgkin's disease, exophthalmic goitre, leukæmia, and other affections.

Frequently diarrhœa arises from the combined action of several exciting causes, as when the disease is epidemic during summer and autumn. Pollution of air, water, and food by foul emanations from organic matter decomposing in very hot weather, overcrowding, food (and especially fruit) in a state of incipient decay, excessive heat, and chills, may then collectively determine the result. In children the exalted irritability of the nervous system during dentition predisposes to diarrhœa from slight determining causes. In several forms of diarrhœa fermentation of the intestinal contents plays an important part—*e.g.* in infantile and summer diarrhœa.

**DESCRIPTION AND VARIETIES.**—Diarrhœa may be broadly divided into the *acute* or occasional, and the *chronic* forms; and the numerous clinical and pathological peculiarities of different cases are conveniently grouped into typical varieties. The general effects, varying according to the intensity and duration of the flux, are mainly these:—Emaciation, and, in children, also arrest of growth—the weight either diminishing or ceasing to be progressive; anæmia, indicating defective hæmatisis; desiccation of the tissues from the rapid draining of serum from the blood—hence the thirst, and the very concentrated, acid, and even albuminous urine observed when there is a copious watery outflow from the bowels, as in choleraic and similar forms of diarrhœa.

It will be expedient to describe briefly the principal forms of diarrhœa.

1. **Irritative Diarrhœa.**—**SYNON.:** *Diarrhœa crapulosa* (Cullen).—Simple flux from direct irritation of the intestines is the most common variety of diarrhœa. The evacuations, usually preceded by severe griping pains, are at first feculent and usually fetid and sour, then watery. In children (especially hand-fed) they are often like pale clay or putty, or they contain dense masses of undigested casein before being loose; after evacuation they frequently become greenish, like chopped spinach, from contact with very concentrated acid urine converting the brown colouring matter of the bile into green biliverdin; or they are dark green when passed, and may be so acrid as to excoriate the anus, the genitals, the inner parts of the thighs, and even the heels. Fever is usually absent.

Diarrhœa from irritation is frequently a preliminary stage of the inflammatory, dysenteric and choleraic varieties.

2. **Inflammatory Diarrhœa.**—**SYNON.:** *Diarrhœa serosa*.—When the causes of simple irritation excite inflammation of the mucous membrane of the bowels, fever sets in, and the diarrhœa increases. Usually the evacuations become more serous, and contain shreds of fibrin or mucus or pus. Before the attack passes off, the large bowel is apt to be the main seat of inflammation; then the motions are scanty, frequent, more mucous or glairy, contain streaks of blood, and are passed with severe straining. At the same time the skin is hot and dry.

3. **Choleraic Diarrhœa.**—**SYNON.:** Choleraic diarrhœa; Thermic diarrhœa. This form prevails mostly in hot weather. The onset, indicated by vomiting and purging, is usually sudden. At first the vomited matters are mucous and bile-tinted, and the dejections are feculent—both quickly, however, becoming more and more abundant, watery, and colourless. The copious and incessant outflow of serum may in a short time, and especially in children, induce a striking resemblance to the symptoms of Asiatic cholera—a drawn, sunken, and cyanotic appearance, loss of temperature, scanty secretion of urine, insatiable thirst, and cramps. Even in extreme cases, however, the fluids from the stomach and bowels are rarely free from bile, and are not so like rice-water as in true cholera. The collapsed algid condition, as a rule, rapidly gives place to recovery in previously healthy adults, while it is apt to become fatal in delicate children, children prematurely weaned, the debilitated, and the aged. Rarely, the cold stage being outlived, the patient becomes hot, and passes into a state of stupor, with either bilious vomiting or purging and tympanites—the typhoid stage. In children death is almost invariably if the cold stage exceeds twenty-four hours.

4. **Nervous Diarrhœa.**—The peristaltic movements, and the activity of the glands, of the alimentary canal, are often increased by causes operating through the nervous system. Diarrhœa from mental, and especially emotional, perturbation, is the most common example. Even a chronic looseness may be maintained by debility of the nervous system, induced by worry and anxiety. Exalted innervation of the bowels may be natural, a proneness to diarrhœa from slight exciting causes having always existed; or acquired, when, for instance, a flux once established is apt to be maintained. The unstable nervous system of the periods of rapid development and of the climacteric change predisposes to it. It is often an important factor in chronic diarrhœa. The intestinal nerve-centres may become so sensitive (as in delicate children) that every meal, however small, may induce an immediate call to stool, the motions being liquid or pultaceous, and pale, but otherwise healthy. The peristaltic movements may be even so increased as to hurry the food through the stomach and bowels, so that it appears unchanged in the stools. Time is not allowed for digestion or absorption to be even begun. This form has been termed *Diarrhœa lienterica*, and is most frequent in children before the period of the second dentition. The increased tonicity of the muscular fibres of the alimentary tract may have resulted from previous inflammation of the mucous surface, or is the propagation upwards of some irritation (ulcer, inflammation, &c.) of the mucous membrane of the rectum; or it arises from the products of imperfect primary digestion entering the duodenum. Indigestion is the usual cause in adults. The appetite is, as a rule, voracious; and debility may become extreme. In painful or difficult dentition, diarrhœa arises from irritation of the nerves of the stomach and bowels; digestion is arrested; and the contents of the alimentary canal become acid from fermentation, and are ejected by vomiting and purging.

5. **Vicarious Diarrhœa.**—Embarrassment or suppression of the functions of the skin, kidneys, or lungs may lead to the bowels performing additional excretory work. The flux thus set up is salutary, because compensatory. Diarrhœa from chills (suppressed perspiration) is a common instance, while that from renal and pulmonary causes is less frequently observed, and may be misconstrued by the practitioner. Inasmuch as diarrhœa usually diminishes the quantity of urine, even sometimes to the verge of suppression, the reverse of this clinical fact may be easily overlooked or misinterpreted. Even when forewarned, the observer may at times—especially when the urine is free from albumen—find it difficult to determine whether the diarrhœa is a cause or an effect of imperfect renal elimination: a distinction

having all-important bearings on the treatment. The uræmic and eliminatory character of it may be easily decided when the kidneys are known to be diseased; not so, however, when the only thing ascertainable is scanty—may be albuminous—urine, or total suppression of urine in an elderly patient. In such a case there may or may not be organic disease of the kidneys, and still the diarrhœa may be uræmic, inasmuch as it may depend on 'renal inadequacy.' Diarrhœa from pulmonary embarrassment generally affords relief to breathing and cough. The chronic looseness of some gouty patients is also eliminatory: when it is checked, gout is apt to advance, and the health to suffer.

6. **Diarrhœa from Mechanical Congestion.**—Draining of serum into the bowels is a common result of overloading of the portal vein from an impediment to the flow of blood, either in the vein itself, the vena cava, or the right side of the heart.

7. **Chronic Diarrhœa.**—**SYNON.:** Cachectic diarrhœa.—Chronic diarrhœa is frequently, if not generally, unconnected with intestinal lesions. It may be maintained by chronic catarrh of the intestines, or by an exhausted and impoverished state of the system, as in inanition, either from insufficiency of food or from enfeebled digestion, or in chronic wasting diseases, such as syphilis, malaria, or scurvy. The flux increasing, the debility on which it depends thereby perpetuates itself, and this vicious circle tends more and more to destroy life by anæmia and exhaustion, and even after apparent recovery the diarrhœa has a strong disposition to relapse. These clinical features of chronic diarrhœa are well illustrated by the malady which, from the paleness of the stools, is commonly known in India as 'White Flux'—a result of deterioration of health by climate and malaria (*see* PSILLOSIS). When accompanied by fever and night-sweats, chronic diarrhœa is nearly always due to tubercularisation.

**DIAGNOSIS.**—The different forms of diarrhœa may be readily distinguished from each other by a careful consideration of the causes and symptoms. The diseases most apt to be mistaken for diarrhœa are epidemic cholera, dysentery, and mucous irritation of the bowels from retention of fæces.

(a) *Cholera*, in its less definite forms, may resemble bilious diarrhœa and choleraic diarrhœa. The probability in favour of it may be determined by the absence of ordinary causes of diarrhœa, the paleness and watery character of the stools, tormina being slight or absent, the suppression of urine, and the early exhaustion. The presence of bile in the stools is always in favour of diarrhœa. Vomiting is more frequent in cholera; when it occurs in diarrhœa the vomited matter usually

contains bile and undigested food, while in cholera it is a colourless fluid.

(b) *Dysentery* is usually characterised by fever, tormina, and tenesmus, and frequent scanty muco-sanguinolent evacuations. Sometimes, however, in the early stage, the motions are copious, watery, and feculent, as in ordinary diarrhœa; but the presence of tormina and tenesmus, and tenderness in the regions of the cæcum and sigmoid flexure, indicate the dysenteric nature of the disease. Chronic diarrhœa may be distinguished from chronic dysentery by the absence of a history of acute dysentery, and of mucus and tenesmus, and by the less frequent discharge of blood in the evacuations.

(c) *Mucous irritation of the bowels* from retention of feces may induce a condition resembling diarrhœa—frequent, thin, muco-feculent evacuations, which are, however, shown, on inquiry, to be somewhat scanty, and voided with straining. See FÆCES, RETENTION OF.

TREATMENT.—(a) *Diet and Hygiene*.—In acute or occasional attacks of diarrhœa, everything should be taken in small quantity, and tepid or cold, never hot. Farinacea—arrowroot, sago, rice, tapioca, flour, and the like—are useful, and may be taken in milk, or in chicken or mutton broth, or weak beef-tea. Animal broths—and especially beef-tea—when concentrated, or in large quantity, are apt to aggravate diarrhœa. Demulcent drinks—white of egg in water or milk, rice or barley or arrowroot water; and astringent liquids—infusion of dried whortleberries or roasted acorns, red light wines—may be given. Brandy is often of service, and may be given in an aromatic water or with the farinacea. Lime-water with milk is in many cases of much value.

Rest in bed secures a uniform warmth of skin, and favours the cessation of diarrhœa.

In children, errors of feeding should be corrected. Lumps of casein in the motions may be prevented by reducing the quantity of milk, or by adding thin arrowroot or barley-water, with or without lime-water or bicarbonate of sodium, to the milk; and by regulating the time between meals, providing a wet nurse, or substituting the milk of the goat or ass for that of the cow. In infantile diarrhœa the milk should be previously boiled and diluted—one part in two or three of barley-water—and given regularly every hour in small quantities (two or three teaspoonfuls). The feeding-bottle, when not in use, should be kept in a weak solution of permanganate of potassium. Sometimes, however, milk in any form must be given up, when barley-water or thin rice-water, sweetened by saccharin or milk-sugar, may be substituted. The abdomen should be protected by a flannel bandage, and the feet and legs by warm clothing. See INFANTS, Diseases of; and DENTITION, Disorders of.

Inasmuch as in chronic diarrhœa the flux is perpetuated by the debility and anæmia which it induces, and by the activity of intestinal digestion, it has become a leading principle of treatment to prescribe food rich in materials for the construction of the blood and the tissues, and almost wholly disposed of by the stomach. Hence the happy results frequently observed from a diet exclusively animal, either raw or lightly cooked, the digestion of which may be aided by hydrochloric acid, alone or with pepsin. Individual peculiarity may be gratified, and variety obtained from the use of mutton, veal, chicken, pigeon, and game. Beef, the tough parts of veal, and pork are, as a rule, to be avoided. Milk and farinacea are gradually permitted during the progress towards recovery, but the period during which they should be interdicted may require to be very prolonged—even months. The treatment with raw meat, strongly advocated by Trousseau and Niemeyer, has been successfully applied to nearly every variety of chronic diarrhœa, but especially to that obstinate form occurring from the time of weaning to the close of the first dentition. The meat may be pounded into a pulp or finely minced; then mixed with salt, sugar, fruit jelly, or conserve of roses; or diffused through clear gravy soup, or chocolate made with water or wine. Or the juice may be extracted from it by pressure. Notwithstanding the prohibition of other food, it is best to begin with a small quantity, and to increase it gradually. The only drink allowable is water containing white of egg. Trousseau found opium in small doses, chalk, and bismuth, at and between meals, to assist this regimen. When a restricted animal diet cannot be digested, causes loathing, or aggravates the flux, other varieties of food may be added, and the feeding should be as generous and varied as possible, and adapted to the digestion of the individual. Articles of diet appearing undigested in the motions should be avoided. Low and damp situations should be exchanged for dry and open ones. Warm clothing, flannel next the skin, and flannel waist-belts should be worn. Chronic diarrhœa (lienteric and chronic tropical diarrhœa) has also been successfully treated by a strict milk diet and rest; and by rest along with massage.<sup>1</sup>

(b) *Medicinal Treatment*.—The kind and degree of interference required should first be decided in each case of diarrhœa. A routine prescription of astringents is much to be deprecated. When the flux is moderate and salutary—for example, removing undigested or indigestible materials or irritating secretions, relieving an engorged portal vein, or supplementing a suppressed secretion—it may be left uncontrolled by medicine, or may be encouraged by laxatives, such as castor oil, rhubarb, or a saline aperient,

<sup>1</sup> Eccles, *Practitioner*, Dec. 1890 and Jan. 1891.

combined with a mild sedative, such as henbane or opium. As a rule, the treatment of diarrhœa should begin by removing irritating substances from the alimentary canal by laxatives, guarded by small doses of opium; and astringents, such as chalk-mixture with kino, catechu, hæmatoxylym, and opium, should be held in reserve. The laxative may increase the flux, which, however, soon subsides. Trousseau advocated the use of salines—sodii sulphas, soda tartarata, magnesi sulphas—in progressively decreasing doses, dissolved in a small bulk of water, in the morning, fasting, while others prefer castor oil, or rhubarb. Castor oil is by far the most useful remedy for children, as well as for adults. For the former it should be emulsified in gum and syrup, for the latter in yolk of egg; and as occasion requires it may be combined with a small opiate, for example, compound tincture of camphor, or the wine or tincture of opium, in proper doses.

In *choleric form* or *summer diarrhœa*, the best results are obtained from castor oil guarded by a small dose of laudanum at the commencement, and repeated if the disease is severe; while astringents and opiates alone are withheld until the bowels are relieved of offensive materials, as in the later stages, the stools being copious and watery, griping and distension of the abdomen absent, and the tongue clean. Vomiting should be encouraged by copious draughts of warm water, and, if need be, by emetics of mustard or ipecacuanha. In children, when the motions are colourless, profuse, and incessant, it is best to give hydragryrum cum cretâ in small doses every hour or two, and a very small enema of starch, containing plumbi acetas or cupri sulphas, with laudanum, which may be repeated if necessary. Remedies which are believed to arrest abnormal intestinal fermentation (such as naphthaline, calomel in small repeated doses, perchloride of mercury, potassio-mercuric iodide, carbolic acid, resorcin, salol, salicylate of sodium) have lately been employed with success in infantile and summer diarrhœa. Dr. Luff has obtained the most gratifying results from potassio-mercuric iodide, preferring the following formula: R Liquoris hydrargyri perchloridi ℥xij.; potassii iodidi gr.  $\frac{3}{4}$ ; chloral hydratis gr. j.; aquæ ad ʒj.; to be given every four hours to infants up to six months, and the dose to be doubled for children of more than one year old.<sup>1</sup> In the cold stage there have been recommended mustard baths (for twelve or fifteen minutes, several times a day); emetics (ipecacuanha 2 to 3 grains twice or three times in twenty-four hours); diffusible stimulants (ether in syrup every hour or half-hour). In the stage of reaction, saline aperients or calomel in small doses may be given; white of egg in water as a drink throughout; and, vomiting having ceased, and diarrhœa

being established, bismuth, chalk or lime-water.

In *nervous diarrhœa* the first indication is to allay reflex excitability by the bromides; or, these failing, by opium. When diarrhœa is excited by food, the dose should be given shortly before meals. In *lienteric diarrhœa* arsenic is invaluable. Mal-digestion should be met by hydrochloric acid, bismuth with alkalis, or other appropriate remedies, according to the indications. Occasional doses of castor oil—alone, or with bismuth or small doses of opium or henbane—are useful in clearing away fermentescible matters, which are apt to maintain an irritable state of the bowels. Astringents should only be prescribed after the failure of these or similar measures.

In *vicarious diarrhœa* the skin should be made to act freely by warm baths, or hot air or vapour baths. In renal inadequacy counter-irritation across the loins, digitalis, and nitrate of potassium may be likewise indicated. The diarrhœa should not be arrested or even checked unless it be profuse and exhausting, especially after restoring or augmenting the action of the skin and the kidneys; it is sometimes advisable to nurse and encourage it.

*Diarrhœa from passive congestion* of the portal vein is to be met by treating the cause, for example, disease of the heart, by digitalis, iron, and other remedies.

The flux of *chronic diarrhœa* (lienteric and the chronic tropical diarrhœa known as sprue or psilosis) cannot, as a rule, be stopped altogether by astringents only—the evacuations while thus retained may decompose, and induce flatulence and colic, or fever. The general health should be restored and anæmia removed; the secretions will then generally improve and the diarrhœa subside. Tonics—iron, arsenic, quinine, strychnine—may be aided by astringents—mineral acids, opium, bismuth, chalk, or hæmatoxylym. The best preparations of iron are iron-alum—3 to 5 grains, and liquor ferri pernitratiss—10 to 40 minims. Ipecacuanha and taraxacum are useful when the skin and liver are inactive: from 1 to 3 grains of powdered ipecacuanha may be given night and morning. Podophyllum—2 or 3 minims of a solution of 1 grain in 1 drachm of rectified spirit three or four times a day—is indicated when the motions are watery, pale or high-coloured, and passed with severe cutting pains. Saline purgatives in the early morning have been recommended—2 drachms of sulphate of sodium, sulphate of magnesium, or soda tartarata on the first day; then 1 drachm for fourteen days, dissolved in a small bulk of water, with avoidance of fluids after the dose. Lately Mr. Begg has reported successful results in the treatment of chronic tropical diarrhœa by santonin (the yellow crystals) gr. v., well mixed in a teaspoonful of olive oil, given in the early

<sup>1</sup> *Lancet*, Dec. 20, 1890.

morning or at bedtime for six days.<sup>1</sup> The profuse sweating and colliquative diarrhœa of hectic is best met by hæmatoxylum and diluted sulphuric acid, or opium with astringent mineral salts—nitrate of silver, sulphate of copper, or acetate of lead—given by the mouth or rectum.

Suppressed secretions, particular cachexiæ, disturbed innervation, congestion of the portal vein, and organic diseases of the intestines, form special indications for treatment when diarrhœa is present.

GEORGE OLIVER.

**DIATHESIS** (*διαθήμη*, I dispose).—A morbid constitution, predisposing to the development of a particular disease. See CONSTITUTION, with which, in a somewhat more limited sense, this term is synonymous.

**DIATHETIC DISEASES.**—Constitutional diseases. See CONSTITUTIONAL DISEASES.

**DICROTISM** (*δῖς*, double; and *κρότος*, a stroke) is a term applied to the second great wave of the pulse. This dicrotic wave, or dicrotism, is due to a second expansion of the artery which occurs during the diastole of the ventricle. The *pulsus bis feriens* of old authors was a pulse in which a second beat became perceptible to the finger; an occurrence observed occasionally as an antecedent of hæmorrhage, and also in the course of fevers. The second beat perceived by the finger is not always the true dicrotic wave, but may in some cases be an exaggerated tidal wave. This is the wave perceived in the high arterial tension sometimes antecedent to hæmorrhage. Dicrotism is favoured by a low state of arterial tension, by elasticity of the arterial coats, and by quick and strong ventricular contractions. It is central in its origin, and is a secondary wave of pressure produced in the blood-column by the elastic recoil of the aorta after its distension by the blood injected at each ventricular systole. The recoil of the aorta causes the wave to spring towards the periphery from the closed aortic valves as a *point d'appui*. See PULSE.

B. WALTER FOSTER.

**DIET.**—DEFINITION.—The term 'diet' as here employed may be understood to express the regulation of food to the requirements of health and the treatment of disease.

**GENERAL PRINCIPLES.**—In order to sustain life, a diet must consist of a proper apportionment of the following alimentary principles:—

1. Nitrogenous principles.
2. Non-nitrogenous principles (fats, carbohydrates, &c.)
3. Inorganic materials (saline matters and water).

Whilst these principles hold different relative positions of value, the absence or deficiency

<sup>1</sup> *Practitioner*, Jan. 1891.

of either group will render a diet unfit for the support of life. Milk, the product provided by Nature as the sole article of sustenance during the early period of the life of mammals, may be regarded as furnishing us with a typical dietetic representative of all these principles. The egg also holds a like position, and, as all the parts of the young animal are evolved from it, must needs comprise all the materials for the development and growth of the body.

The required principles are contained in food derived from both the animal and vegetable kingdoms, and the diet may be drawn from either; but, looking to man's general inclination and the conformation of his digestive apparatus, it may be assumed that a mixed diet is that which is designed in the plan of Nature for his subsistence, and it is that upon which he attains the highest state of physical development and intellectual vigour.

Animal food, being identical in composition with the body to be nourished by it, is in a state to be more easily appropriated than vegetable food. It also appeases hunger more thoroughly and satisfies longer: in other words, it gives, as general experience will confirm, a feeling of greater stay to the stomach. Animal food possesses stimulant properties which have sufficed in certain instances, as after starvation, and in those accustomed to a vegetable diet, to produce a state allied to intoxication. This stimulating effect is further illustrated by looking at the relative character of animal and vegetable feeders. Liebig says that it is essentially their food which makes carnivorous animals in general bolder and more combative than the herbivora which are their prey. He then relates that a bear kept at the Anatomical Museum of Giessen showed a quiet gentle nature as long as it was fed upon bread, but a few days' feeding on meat made it vicious and dangerous.

The standard diet framed by Moleschott has been accepted as furnishing a model of what may be considered the requisite proportion of alimentary principles for maintaining health in a person of average stature under exposure to a temperate climate, and the performance of a moderate amount of muscular work. It runs as follows:—

*Alimentary substances in a dry state required daily.*

Dry Food	In ounces avoird.
Albuminous matter . . . . .	4·587
Fatty matter . . . . .	2·964
Carbohydrates . . . . .	14·250
Salts . . . . .	1·058
	<hr/>
	22·859

This, it will be seen, furnishes a supply of about 23 ounces of dry solid matter, of which

one-fifth is nitrogenous. If we reckon that ordinary food contains about 50 per cent. of water, then 23 ounces will correspond to 46 ounces of solid food in the condition in which it is consumed. To complete the alimentary ingesta, a further quantity of from 50 ounces to 80 ounces of water may be assumed to be required to be taken daily under some form or other.

For a life of inactivity, it must be stated that a much smaller amount of food will suffice. The diet, for instance, which is ordinarily supplied to the patients of Guy's Hospital, and which suffices to satisfy and properly sustain them, only contains about 30 ounces of solid food, equivalent to about 17 ounces of water-free material.

It has been mentioned that there are reasons for regarding a mixed diet of animal and vegetable food as best adapted to our nature, and it may probably be considered that the most suitable admixture contains about one-fourth or rather more of animal food.

Looked at from the following point of view, it will be seen that an admixture of animal and vegetable food more economically supplies what is wanted than either kind taken alone, unless the adjustment should be made with the proper apportionment of fat as a representative of a non-nitrogenous article. It is estimated that for a man of medium stature, and performing a moderate amount of work, about 300 grains of nitrogen and 4,800 grains of carbon are required to be introduced daily into the system with the food, to compensate for the outgoing of these elements that occurs. Now this is yielded, as nearly as possible, in the case of both elements, by 2 lbs. of bread and  $\frac{3}{4}$  lb. of meat—that is, 44 ounces of solid food, of which about one-fourth consists of animal matter. If the lean of meat only were consumed, rather over 6 lbs. would be needed to furnish the requisite amount of carbon, and there would be a very large surplus of unutilisable nitrogen; whilst if bread only were taken, the amount necessary to supply the requisite quantity of nitrogen would be rather more than 4 lbs., and this contains nearly double the amount of carbon wanted.

In order to preserve health it is necessary that a portion of the food consumed should be in the fresh state, and this applies to both animal and vegetable food. There may be no lack of quantity, and yet disease and death may be induced by inattention to this fact. Affections of the scorbutic class are produced, which can only be checked and removed by the supply of fresh food or the juice of some kind of succulent vegetable or fruit. The efficacy of lemon and lime juice, for instance, is well known in the prevention and cure of scurvy.

Climate influences the demand for food, and instinct leads to the adaptation of diet to the

requirements that exist. Not only is there a correspondence between the amount of food required and the inclination for taking it, but the nature of the food selected in different countries varies and stands in harmony with that which is most in conformity with what is needed. The dwellers in the arctic regions, besides consuming a large quantity of food, partake of that kind which abounds in the most efficient form of heat-generating material—namely, oleaginous matter. In the tropics, on the other hand, it is upon vegetable products, largely charged with principles belonging to the carbohydrate group, that the native inhabitants mainly subsist.

Labour necessitates a supply of food in proportion to the amount of work done. The employer finds that the appetite of a workman may be taken as a measure of capacity for work—in other words, that a falling off of the appetite means a diminished capacity for the performance of labour.

Until recently it was considered, in accordance with the teaching of Liebig, that muscular and nervous action resulted from an oxidation of muscular and nervous tissue, and that according to the amount of action occurring, so was there created a demand for the supply of nitrogenous alimentary principles to replace the oxidised material. It is now held, however, that the non-nitrogenous elements of food contribute, as well as the nitrogenous, to the production of muscular and nervous force. Fick and Wislicenus undertook a known amount of work upon a non-nitrogenous diet, and proved that the oxidation of their muscular tissue, as measured by the amount of nitrogen voided with the urine, sufficed only for the production of a small proportion of the force expended in the accomplishment of the work performed. The muscles, in reality, appear to stand in the position of instruments for effecting the conversion of the chemical energy evolved by the oxidation of combustible matter into working power. Fats and carbohydrates can furnish the combustible matter required, and, under ordinary circumstances, probably do largely, if not chiefly, supply it. Nitrogenous matter can do so likewise, but it has to undergo a preparatory metamorphosis for effecting the separation of nitrogen in a suitable form for elimination. It must be said, however, that experience shows that hard work is best performed under a liberal supply of nitrogen-containing food. The explanation of this probably is that it leads to a better-nourished condition of the muscles and of the body generally. Under the use, for instance, of animal food, which is characterised by its richness in nitrogenous matter, the muscles are observed to be firmer and richer in solid constituents than under subsistence upon vegetable food.

Persons who lead a sedentary and indoor

life naturally require less food than those engaged in active work, and less should be consumed by them to prevent the system becoming clogged with effete products, which act perniciously in various ways upon the body. The food should also be largely constituted of non-nitrogenous principles, as these tax the excretory organs less than the nitrogenous.

The diet of *infants* is a branch of dietetics the importance of which can scarcely be overrated. The proper food during the first period of infancy is that which has been provided by Nature for the young of mammals—namely, milk. Up to about the eighth month the infant is designed to be sustained solely by its parent's milk. The teeth, which ordinarily begin to show themselves about this time, indicate that some solid matter should now be consumed, and one of the farinaceous products will be the most suitable with which to commence. Bread, baked flour, plain biscuit, or one of the numerous kinds of nursery biscuits that are made, may be employed for a time as a supplement to the former food. At about the tenth month the mother, who ought previously to have commenced lessening her own supply, should now cease it altogether. As the child advances through its second year, and the teeth become more developed, meat, preceded for awhile by gravy, may be given. If the mother cannot suckle her child, and if a wet nurse, whose supply stands next best to that of the mother, cannot be provided, the milk of one of the lower animals should be obtained, and that of the cow gives the nearest approach to what is wanted. Cow's milk, however, is richer in all its solid constituent principles than woman's, and the addition of a solution of sugar or—what is more in conformity with the natural supply—sugar of milk (lactose), in the proportion of an ounce to three-quarters of a pint of water, is needed to bring the two into closer approximation. The milk of the goat is even richer in solid constituents than that of the cow, and therefore stands somewhat further removed from that of the human subject. If, however, it is not adapted for infants, it is highly useful for improving the condition of badly nourished children, and is sometimes employed for this purpose.

**THERAPEUTICAL APPLICATIONS.**—The application of the principles of dietetics may be successfully brought into use in the treatment of corpulency and thinness. A diet rich in nitrogenous matter, conjoined with exercise, promotes the growth of muscle, but the fat undergoes no increase. The conditions most conducive to an increased accumulation of fat are a diet rich in either fat or carbohydrates (provided the requisite amount of nitrogenous matter be present for affording what is wanted for the nutritive operations of life), exposure to a warm atmosphere, and inactive habits. A supply of fat in a

direct manner leads to an increased deposition of fat in the system, but the carbohydrates require in the first place to undergo assimilative change before they can be applied in the same direction.

The details of the dietary to be prescribed where the aim is to produce increased stoutness and an improved condition of the body, should comprise such articles as fat meats, butter, cream, milk, cocoa, chocolate, bread, potatoes, farinaceous and flour puddings, oatmeal porridge, sugar and sweets, sweet wines, porter, stout, and ales.

The converse mode of dieting is necessary for reducing stoutness. Mr. Banting, by his noted system of dieting, reduced his weight from 14 st. 6 lbs. to 11 st. 2 lbs. in about a year. Besides altering, however, the character of his food, he limited the quantity in a manner that must have contributed an important share towards producing the effect observed—not more than twenty-two to twenty-six ounces of solid food (corresponding with eleven to thirteen ounces of water-free material) being consumed, according to his statement, in the twenty-four hours.

As a guide to the corpulent, it may be said that the fat of meat, butter, cream, sugar and sweets, pastry, puddings, farinaceous articles—as rice, sago, tapioca, &c., potatoes, carrots, parsnips, beetroot, sweet ales, porter, stout, port wine, and all sweet wines, should be avoided, or only very sparingly consumed. Wheaten bread should only be partaken of moderately, and brown bread is to some extent better than white. The gluten biscuits which are prepared for the diabetic may, on account of their comparative freedom from starch, be advantageously used as a substitute for bread in the treatment of obesity. The articles that may be taken to the extent of satisfying a natural appetite are lean meat, poultry, game, eggs, green vegetables, succulent fruits, light wines, dry sherry, and spirits. Milk should only be taken sparingly.

Holding the position that food does in relation to the operations of life, the art of dietetics not only bears on the maintenance of health, but is capable of being turned to advantageous account as a therapeutic agency; and it is not too much to say that success in the treatment of disease is oftentimes dependent upon a display of judicious management in regard to food.

In the therapeutic application of dietetics the maxim should be held in view that, whilst the particular requirements are secured, there should otherwise be no greater deviation from what is natural than the special circumstances of the case demand.

The quantity of food consumed may require to be regulated as well as its nature. The quantity administered at a time should stand in relation to the power of digesting it; and to properly compensate for a diminished capacity for taking quantity there should be

a corresponding increase in the frequency of administration. 'Little and often' is the maxim to be followed upon many occasions, and much will sometimes depend upon the strictness with which it is acted up to; for, apart from harmonising with what is wanted, upon the principle that has just been referred to, it meets the defective aptitude that exists in sickness for sustaining any lengthened duration of abstinence from food.

In febrile, acute inflammatory, and other conditions where there is a failure of digestive power, the food administered should be such as not to tax the stomach, and should therefore consist of liquid materials. Solid matter by remaining undigested—and solids of an animal nature are particularly likely to do so—would act as a source of irritation in the stomach, and only serve to aggravate the condition of the patient. The articles under such circumstances to be selected from are beef-tea, mutton-, veal-, or chicken-broth, whey, calf's-foot and other kinds of jelly, arrowroot and such-like farinaceous articles, barley water, rice mucilage, gum water, fruit jelly, and the juice of fruits, as of lemons, oranges, &c., made into drinks. Where a little latitude is allowable, the employment of milk and of eggs in a fluid form may be sanctioned. As circumstances permit, an advance may be made to solid substances which do not throw much work on the stomach, as rice, sago, tapioca, bread and custard puddings, and stale bread or toast sopped. Next may be allowed fish, beginning with whiting. As power becomes restored, calves' feet, chicken, game, and butcher's meat—mutton to begin with—may be permitted to follow.

In cases of ordinary dyspepsia the aim of the physician should be rather directed to raising, by appropriate treatment, the digestive capacity to the level of digesting light but ordinary food, than to reducing the food to an adjustment with a low standard of digestive power. Of butcher's meat, mutton is almost invariably found to be the most suitable; chicken and game are allowable, also white fish (boiled or broiled), particularly whiting, sole, flounder, and plaice. Stale bread, dry toast, plain biscuits, floury potatoes, rice, and the various farinaceous articles form the kind of food derived from the vegetable kingdom to be selected. Green and other succulent vegetables, it is found, are more apt to create flatulence than other kinds of food, and articles belonging to the cabbage tribe are particularly to be regarded as obnoxious to those who have a tendency to this form of derangement.

Much depends in cases of weak digestion upon the state in which the food reaches the stomach. Thorough mastication affords great assistance to the performance of digestion; and when the teeth are bad, the food should be finely minced, or otherwise minutely divided, before being eaten. Regularity in

the periods of taking food tends to promote the orderly working of the digestive organs. An interval of more than four or five hours' duration between the meals is to be avoided, as it acts perniciously in several ways. By inducing an exhausted state of the system it diminishes the energy of the digestive organs, and whilst having this effect it at the same time calls for the periodical exercise of increased energy, on account of the larger amount of food which must be taken at each meal to compensate for the length of time that is allowed to elapse between them.

In cases of ulcer of the stomach, acute gastric catarrh, and vomiting, the food must be selected from that which is nutritious and which at the same time taxes least the digestive powers. Milk—and this is often better borne after being boiled—milk and water, or milk and soda-water, will frequently be found to be tolerated when other articles excite irritation and are returned. Sometimes the milk may be advantageously mixed with isinglass, arrowroot, ground rice, or biscuit powder.

In dysentery and other forms of ulcerative disease of the intestine, scrupulous attention must be paid to diet. The food should consist of articles which are known to exert the least stimulant and irritant action on the mucous membrane and muscular coat of the alimentary canal, and those which best meet the demand in question are such as milk, isinglass, and the various farinaceous products, amongst which rice is pre-eminently valuable. Next to these come eggs, white fish, white-fleshed poultry, fresh game, and fresh meat. Salted and dried meats are highly objectionable, and fruits and succulent vegetables, with the exception of a floury potato, should be strictly shunned. *See PEP-TONISED FOOD.*

The development of gout is known to be favoured by the consumption of a highly nitrogenised diet, especially if conjoined with sedentary habits. With those who have already experienced symptoms of the disease, and those also who have grounds for apprehending its invasion, it is important that an excess of nitrogenous food should be avoided. The diet should be simple, in order that the temptation may be avoided of eating too much, and should at the same time be adjusted to the mode of life. The principle to observe is that the higher the degree of inactivity the greater ought to be the preponderance of food derived from the vegetable kingdom.

Even of more importance than what is eaten is what is drunk, where the question of gout is concerned; and observation shows that it is not distilled spirits, but the stronger wines and malt liquors, which favour the production of the disorder. Nothing is more potent than port wine in leading to the production of gout, and a few years' liberal indulgence in it has often been known to be

instrumental in bringing on the disease where no family predisposition had existed. Dry sherry and the light wines, as claret, hock, &c., may be drunk, certainly in moderation, with comparatively little or no fear of inducing the disease, although any kind of wine appears capable of sometimes acting as the exciting cause of a paroxysm where the gouty disposition is already established. Stout, porter, and the stronger ales, especially those that have become hard from age, rank next to port wine in their power of predisposing to gout. As regards the light bitter beers, which are so extensively used at the present time, the same must be said of them as of the light wines, viz. that with little, if any, disposition to induce the disease, they nevertheless appear capable of sometimes exciting its manifestation in a gouty subject. A pure spirit, as whisky, hollands, or brandy, diluted with water, often forms the only kind of alcoholic drink that is found to agree with those who are suffering from gout.

In Bright's disease with threatening uræmic poisoning it is a point of consideration to diminish as far as practicable the amount of excretory matter to be eliminated by the kidneys. The fats and carbohydrates throw no work upon the kidneys. Their products of destruction escape through another channel. Nitrogenous matters, on the other hand, undergo metamorphosis in the system, and yield nitrogen-containing compounds—chiefly urea—to escape by the kidneys. In this way the kidneys become taxed by nitrogenous food, and, to lessen the work demanded of them, reason suggests that the diet should preponderate in food derived from the vegetable kingdom.

In diabetes mellitus there is a want of assimilative power over the saccharine and starchy principles of food. Whilst these principles become utilised and lost sight of when ingested by a healthy person, in the system of the diabetic they fail to become consumed, but pass off under the form of sugar in the urine, giving rise to severity of symptoms in proportion to the amount of sugar escaping. Much may be done towards subduing the symptoms of the disease by a properly arranged dietetic scheme, and the principle upon which it requires to be framed is the exclusion, as far as practicable, both from what is eaten and what is drunk, of articles containing saccharine or starchy matters.

Observation has shown that the reaction of the urine is susceptible of being influenced by the character of the food. The effect of animal food is to increase the acidity of the secretion, whilst that of vegetable food is to diminish it, and even, it may be, to produce alkalinity. Hence, on persons affected with the lithic-acid diathesis, benefit is conferred by a plan of diet in which animal food is

limited, and succulent vegetables and fruits, with the light wines, as claret, hock, &c., are freely supplied. On the other hand, with the phosphatic diathesis, the converse principle of action should be adopted.

F. W. PAVY.

**DIGESTION, Disorders of.**—The function of digestion is of a physico-chemical nature, being compounded of certain muscular acts, and of certain processes exercised by the digestive fluids on the ingesta, which are thereby converted into a fluid and diffusible state.

Any interference with the due performance of the several components of the function will lead to indigestion; and though it may for convenience be desirable to consider these disturbances separately, it must be remembered that the occurrence of one condition is apt to be quickly associated with another, and hence the forms of dyspepsia as they usually present themselves are of a complex nature, however simple the primary fault may have been. It appears to the writer to be very undesirable to restrict the application of the term *indigestion* or its synonym *dyspepsia* to the perverted actions of any one part of the alimentary system, such as the stomach, or to any one special morbid state, such as gastric or intestinal catarrh; but rather that it should include all departures from normal function which any part of the digestive tract may present. Nor is it possible to consider irregularities of digestion only from the point of view of the organs immediately concerned. Complicated as our organism is, disturbances of other functions will speedily make themselves felt in the one under consideration; and failures in the absorption of the digested food, or in its subsequent metabolic changes and elimination, will tell back sooner or later on that process which is, strictly speaking, limited to its preparation.

**CAUSES OF DYSPEPSIA.**—Dyspepsia may be immediately traced to (1) *the food*; (2) *disturbances of the so-called mechanical processes*—namely, the muscular acts, solution, &c.; (3) *deficiencies in the chemical changes* exercised by the digestive secretions; or (4) *imperfect absorption* of digested products. It is to be understood that the three last-mentioned groups of causes which bring about indigestion are determined by certain gross or minute abnormal changes in the structural tissues of the organs concerned, as described in the article DIGESTIVE ORGANS, Diseases of the.

**1. Imperfections of Food.**—Imperfections of food, whether in quality or quantity, are among the most frequent causes of digestive disorders. A thorough knowledge of the principles of dietetics is essential, that the errors may be recognised and remedied. Since our digestive capability is limited, it

is obvious that, when those limits are overstepped, the domain of disease is entered upon; and although no very absolute lines may be laid down for universal application, the general rules for quantity and kind are capable of being stated. *See* DIET.

(a) *Deficiency of Food.*—Except under rare conditions, such as famine, &c., this is not a common cause of disease. Of the signs and symptoms of starvation it is not needed here to treat. But there are frequent occasions when, with no deficiency in the total bulk of food taken, there is yet a serious want in one or perhaps more of the needful alimentary principles, and this is especially liable to occur in the feeding of children. Setting aside those gross cases of cruelty, when infants and the youngest children are fed almost from their birth with bread, broth, or even meat, there are still too often to be met with children whose diet-scale is almost entirely wanting in nitrogenous matter. Fed chiefly upon infants' foods, the latter consisting of little more than starchy material, their tissues are ill-formed for the want of proteids, which, during the period of growth, are required in a larger relative proportion. The relationship of rickets to prolonged suckling, with the accompanying deficiency in necessary food-stuffs, is now generally recognised.

The effect of a deficiency of food is a general state of malnutrition, in which any hereditary tendencies to disease that may exist have a more favourable field for development. There is a gradual diminution in the weight of the body, and an imperfect performance of its functions, as indicated by muscular weakness, mental lassitude, &c.

The specially dyspeptic symptoms referable to a want of food are, mainly, perversions of sensation, such as a feeling of sinking, emptiness, or even pain at the epigastrium, or generally in the abdomen. Constipation is frequent from lack of stimulus to normal peristalsis, and it is probable that the digestive secretions are defective in quality and quantity, thereby causing imperfect digestion of the food that is taken. A weak digestion is not seldom due to want of the needful stimulation of sufficient food.

The deficiency in food taken may result not so much from a defective supply of nutriment, as from a disinclination to eat, a common symptom of many diseases, especially febrile states; self-imposed fasting too frequent or prolonged; the anorexia of the hysterical temperament; or from obstruction to the entrance of food into the stomach from stricture of the œsophagus. Or the appetite may be impaired by over-indulgence in alcohol or tobacco. *See* APPETITE.

(3) *Excess of Food.*—There is very little doubt but that more food is daily in the habit of being taken than is actually required to restore the tissue-waste, most active lives

being led on an amount far below what is ordinarily regarded as being necessary; and there is equally little doubt that much of what is taken is not in the most digestible form. It is open to question whether the appetite would be satisfied by the ingestion of merely sufficient to balance the waste, particularly if the gross bulk of the food taken were diminished by the removal, as far as possible, of all indigestible matters, leaving little more than the needful alimentary principles. At the same time it must not be forgotten that the appetite is very easily controlled by custom, and determination can in time overcome a vicious habit.

An habitual excess of food, at least in this country, usually errs in the disproportionate amount of nitrogenous matter it contains. Remembering the relatively small quantity of this principle that is essential, and in what a number of the ordinary articles of diet it occurs, this statement will be the more readily accepted. Since all the proteid principles require, to fit them for absorption into the blood, a considerable amount of chemical alteration, and, physiologically speaking, there is good reason to believe that the subsequent metabolic changes of these matters, when absorbed, are more complex than those undergone by fats and amyloids, it would follow that the organs concerned in effecting these changes are very prone to suffer from overwork and its sequelæ. Also many of the substances resulting from the metabolism of nitrogenous matter are liable to become positive poisons in the economy, and the proper elimination of such materials is specially provided for by such organs as the kidneys and skin. The frequency with which these organs become the seat of disease may at least indicate the probability of errors of diet being an important factor in determining the morbid changes, especially as considerable relief is often the result of a restriction of nitrogenous food. There can be little doubt but that the large group of diseases associated with failure in elimination of nitrogenous waste has for a prominent cause an habitual excess of nitrogenous food.

The results of an excessive ingestion of food are as numerous as they are diverse. In many cases there does not seem to be either impairment of health or shortening of life. In some obesity and in others leanness ensues. In a large majority of individuals whose food is much in excess of their wants, particularly if the exercise taken be but little, there are variable symptoms of indigestion, such as a general feeling of lassitude and want of energy, both muscular and mental, a liability to headaches chiefly frontal, constipation, or more rarely diarrhœa, high-coloured urine depositing abundance of urates, a general disposition to sleep, various skin-eruptions, particularly acne, and not

infrequently a feeble heart's action from commencing fatty degeneration of its substance. Any or all of these symptoms may exist, and may be more or less completely relieved by a restricted diet. It is impossible to lay down any exact rules for the quantity of food that should be daily consumed; though it is desirable to remember that the tendency is to take too much, at the same time that age, season of year, and occupation are all circumstances determining variations both in quantity and kind.

(7) *Improper Food.*—Setting aside those extreme cases of perverted appetite occasionally seen in the hysterical condition, there yet remains a very constant violation of the dietetic proprieties. These errors may be classed under the following heads:—1. Substances which are indigestible; either essentially so, or from imperfect preparation (cooking, &c.) 2. Substances which, though digestible, are innutritious or even poisonous. In the first group are included such bodies as the pips and seeds as well as the skins and rinds of fruits, the husks of corn and bran, the stalks and fibres of leaves, and gristle, elastic tissue, and hairs in animal food. For the reducing of these to a fluid and diffusible condition no chemical arrangement exists in the human organism, and they are voided very much in the same state as they are swallowed. Many articles of diet depend in great part for their digestibility on their proper preparation by division, cooking, &c. Thus most vegetables when taken in the raw state are but imperfectly digested, and such nutritious food as potatoes becomes when uncooked positively harmful. The apparent value of raw green vegetables, as lettuce, endive, cress, &c., would seem to depend on the peculiar condition of their mineral constituents, rather than on the vegetable tissues. Such substances as the above-mentioned are apt to produce perversions of digestion in virtue of the mechanical irritation they give rise to, indicated by more or less pain of a gripping character (colic), and frequently accompanied by diarrhœa. The constant indigestion of the more formidable may even set up a gastro-enteritis, acute or chronic. Occasionally articles of food, such as brown bread, oatmeal porridge, &c., are taken for the very aperient action they induce, owing to the irritating nature of the indigestible husks they contain. Symptoms of acute dyspepsia very frequently follow the taking of meat foods enveloped in greasy sauces, since the fat, being undigested in the stomach, prevents the action of the gastric juice on the proteid matter, which then passes on into the intestines, setting up irritation like any other indigestible substance. The most interesting among those articles of diet which, though easily digested, may be poisonous, are those producing their effects only on certain individuals. Such, for example, are certain

mushrooms, shell-fish, or indeed any fish. Remarkable cases are authentically recorded of serious and even fatal results following their ingestion. The symptoms may be those of an acute gastro-enteritis; or, as is very frequently the case, an urticaria is the result, with or without swelling of the eyes and throat. Severe nervous prostration has been met with occasionally. Be it understood that other people have partaken of the same diet with no ill results. The writer is acquainted with a gentleman who for many years was unable to remain in the room when fish of any kind was on the table, its presence inducing severe vomiting, abdominal pain, and general illness; and although the effects are now but slight from the mere smell of such food, very marked symptoms follow on partaking of any. The most digestible and nutritious articles of food may determine indigestion when taken too hot or too cold.

Finally must be included those substances which accidentally find their way into the alimentary canal with the food, as entozoa, ergot of rye, pins, needles, coins, buttons, &c., or lead and other poisons off the hands of workers in them, all of which give rise to definite and for the most part characteristic symptoms.

**2. Irregularities of the Mechanism of Digestion.**—The motor factors of the digestive process depend for their due and normal performance on the integrity of the muscular tissue, the nerve-centres, and the connecting nerves. The several stages of the entire process are mastication, deglutition, the churning movements of the stomach, the peristaltic action of the intestines, and defæcation. Each of these is liable to impairment, in the direction of increased activity, or of deficiency (paralysis), due either to lesions, or to reflex stimulation of the nerve-centres whence the motor stimuli emanate, of the nerve-fibres by which these stimuli are conveyed, or of the muscular tissue by which the movements are performed. Not infrequently more than one of these tissues may be at fault.

Lastly, obstructions to the movements may be caused by tumours, cicatrices, adhesions to adjacent structures, &c. Irregularities of mastication, deglutition, and defæcation are fully considered elsewhere.

(1) *Paralysis.*—Apart from possible structural affections of the intrinsic nervous mechanism of the gastro-intestinal tract—Auerbach's plexus—of which, indeed, little is known, arrest of the peristaltic action of the gullet, stomach, or intestines is undoubtedly often associated with diseased conditions of the central nervous organs; but the exact connexion is far from being satisfactorily determined. Those lesions which interfere with the action of the vagus nerve, and remove its accelerating influence over the peri-

staltic movements, have been regarded as most likely to bring about this condition; but stimulation of the splanchnic nerves, by which inhibitory impulses reach the stomach and bowels, will produce the same result. The nervous exhaustion induced by long fasting, continued vomiting, previous violent peristalsis from purgatives, hysteria, and such diseases as chronic anæmia, typhus, and puerperal fever; also over-brainwork, with the attendant altered conditions of cerebral vascularity, and extremes of blood temperature in pyrexia, or great cold, have been found to be accompanied with symptoms indicating loss of power of the muscular coat of the bowel. Possibly in these cases the result is due to arrest of the vagus influence.

Paralysis of the stomach and intestines is a frequent result of affection of these organs themselves. Inflammation of the peritoneal or mucous coats, with the subsequent infiltration of the muscular coat with the inflammatory products, materially diminishes the power of the contractile tissue. Degeneration of the organs, particularly the lardaceous variety, which, commencing in the mucous, subsequently invades the muscular coat, obviously interferes with the movements. Over-distension from whatever cause will also enfeeble the contractile power of the muscular fibres of the stomach or intestine, whilst moderate distension is the normal stimulus to their activity. If, as is supposed, the energetic contractions of the pyloric part of the stomach, whereby the chyme is propelled into the duodenum, be normally excited by the acidity of the gastric juice, it may be expected that any diminution of this acidity will lead to deficient propulsion of the contents, and their undue retention in the stomach. The movements of the alimentary canal may be considerably lessened by the administration of certain drugs, such as opium, which diminish the excitability of the augmentor centres, or stimulate the inhibitory control.

The results of these various paralytic affections are in most cases sufficiently apparent. The palsied lips and cheeks and tongue tell their own tale by the half-opened mouth, the dribbling saliva, and the cheeks distended with food which cannot be kept between the teeth. When the fauces and pharynx are affected, the painful efforts at swallowing, the rejection of food through the nose, and the passage of food into the larynx, are signs not to be mistaken. Paralysis of the stomach and intestines is mainly recognised by the constipation from inability of the canal to propel its contents, and by symptoms of dyspepsia, such as flatulence due to deficient gastric secretion from want of the requisite stimulation afforded by the churning of the stomach-contents, and to consequent delayed digestion, leading to abnormal fermentative changes. A paralytic condition of the

sphincter ani will be indicated by an inability to retain the fæces. It should not be forgotten that, normally, the gastric movements cease during sleep.

(2) *Excessive activity*.—Excessive activity of the muscular structures of the alimentary canal will be manifested by an increased peristalsis of the stomach and intestine, or by tonic spasms of limited regions. The former condition, by hurrying along the contents at the expense of their proper digestion and absorption, is an effective cause of diarrhoea. The latter, which is altogether abnormal and not a mere exaggeration of a healthy action, will, in proportion to its severity and extent, determine obstruction to the passage of the food. The spasmodic affections are almost always associated with pain—intestinal cramp, colic, tormina, &c.; and varying degrees of discomfort usually accompany exalted peristalsis.

The causes leading to these states may, as in paralysis, be referred (a) to the cerebro-spinal centres, or (b) to the local neuro-muscular structures. Excluding spasms of the muscles of mastication, deglutition, and defæcation, which are elsewhere treated of, increased gastro-intestinal movements (a) may follow on (i.) emotional states; (ii.) some structural lesions of brain and spinal cord, such as basilar meningitis and locomotor ataxy; (iii.) the increased excitability of the neuro-muscular apparatus caused by drugs—as strychnine, and septic poisons; (iv.) cutaneous irritation, as from cold, reflexly stimulating the accelerator nerves; affections of other viscera, especially uterine and ovarian, may act in a similar manner. Whilst the first- and last-mentioned causes tend to cause increased peristalsis of the canal, the other causes mentioned rather lead to tonic spasm.

(b) Causes which may be regarded as exciting gastro-intestinal movements by their local effect may be grouped thus: (i.) irritation due to the character of the contents, such as its indigestible nature, acidity, extreme coldness or even excessive bulk, foreign bodies in the food, as pins, buttons, &c., irritant drugs, or worms; (ii.) drugs which appear to act directly on the gastro-intestinal plexuses and muscle-fibres, as lead, nicotine, &c.; (iii.) increased irritability of the mucous surface, as from inflammation or ulceration, thereby favouring the action of the ordinary stimulants to contraction. Certain blood-states, such as that occurring in the uric-acid diathesis, anæmia, or any other condition in which there is a deficiency of circulating oxygen and overcharge of carbonic acid, are liable to excite spasm or increased peristalsis, probably acting on the nerve-centres concerned, as well as directly on the tissues of the canal itself. Spasm of the pylorus, described as of occasional occurrence, is of theoretic rather than practical interest; a paralytic state of this sphincter is probably

more common. The normal tonicity of the sphincter ani may give place to painful spasm, a condition which is very apt to complicate fissure and ulcer of the anus.

(3) *Mechanical difficulties.*—The due performance of the mechanism of digestion may be interfered with by alterations in the condition of the alimentary canal caused by various kinds of obstruction or dilatation. Thus deglutition may be rendered difficult or even impossible by a swollen tongue or tonsils, post-pharyngeal abscess, tumours of the oesophagus or larynx, or new-growths situated at the cardiac aperture of the stomach. The various obstructive diseases of the pylorus and intestines will obviously interfere with the proper passage of the contents, and in those dilatations of the canal which are liable to develop above a stricture, the food accumulates and is delayed in its passage. The adhesion of coils of the bowels to each other or to adjacent structures is a further source of imperfect movement.

(4) *Diseases of the teeth.*—Lastly, the subdivision of the solid food, so necessary for the effective action of the digestive juices, is only imperfectly performed when the teeth are deficient in number or are carious, and to this cause a large proportion of cases of dyspepsia may be fairly assigned.

So marked a perversion of the mechanism of digestion as vomiting is more fitly described by itself, though it is a very frequent symptom of indigestion.

3. *Imperfections in the Chemical Changes.*—Our knowledge of the normal chemistry of digestion, much as it has advanced of late, is still very far from complete; and, in face of our ignorance, but little can be said of the conditions existing in disease. Yet there are certainly no departures from the healthy working of the body so common as are those associated with the digestion of the food.

The various secretions, whose office it is to convert into a fluid and diffusible form those alimentary principles which cannot be absorbed without such preparation, are formed from the blood by the salivary, gastric, pancreatic, hepatic, and intestinal glands. It is clear that, for these juices to be secreted in proper quantity or of proper composition, the blood, no less than the secreting cells, must be in a healthy condition, and the trophic influence of the nervous centres upon the latter must be unimpaired. If the circulating fluid be laden with imperfectly secreted products of tissue-change, or if it be charged with poison, of whatever origin, it is not to be expected that a normal secretion is to be obtained from it; whilst, on the other hand, a degenerated secreting epithelium is unable to perform a function intimately dependent on the integrity of its protoplasm. Of necessity these two factors—blood and cells—react on one another; any flaw in the one is reciprocated by the other, and thus becomes

intensified by mutual interdependence. Experiment leads us to ascribe the efficacy of these juices in the changes they effect to the existence in them of certain so-called ferments, whilst the result they bring about is mainly one of hydration. How far the various mineral constituents of the secretions aid in the process is uncertain, but at least their presence cannot be dispensed with. In this way, the insoluble starches of our food are converted by the saliva, the pancreatic, and possibly the intestinal juices, into soluble and diffusible sugars; the various proteids are rendered capable of absorption into the blood, by the gastric and pancreatic juices, and perhaps also the succus entericus, being changed into bodies known as peptones. The fats are prepared for absorption by the bile and pancreatic juice, by being in part reduced to a sufficiently minute state of subdivision (emulsion) to permit of their passage through the tissue-interstices, and partly by being chemically altered into soaps. However closely we may imitate the separate actions of these fluids in our test-tubes and laboratories, the conditions are undoubtedly much more complicated in the alimentary canal, where so many changes are simultaneously going on, and so many sets of products are formed.

The various secretions may be morbidly affected in respect to their quantity or composition; alterations which must of necessity profoundly modify the digestive process, though with our present imperfect knowledge we may not be able to refer with accuracy any particular symptoms of indigestion to a special change in either of the secretions.

The *saliva* may be increased in amount (*see SALIVATION*), the fluid being poor in solids and ferment. It may be difficult to trace any definite digestive troubles to this condition, since there is no evidence that the carbohydrates are insufficiently converted; but it is probable that the quantity of slightly alkaline fluid swallowed may interfere with the changes in the stomach. The general wasting which frequently follows on this state may be in part attributable to the anorexia which is so commonly associated with it. Nor can a diminution in the saliva, such as occurs in fever, be held responsible for any special dyspeptic symptom. Should the fluids of the mouth become acid, as from lactic or other fermentation of food therein, a stomatitis of varying severity may be induced, so commonly seen in infants.

Within the past few years considerable attention has been paid to the behaviour of the *gastric juice* in disease, and much valuable information has been obtained, mainly in reference to the acid constituents. The want of a reliable test for the acids has been felt, but for all ordinary practical purposes, so far as present investigation has gone, Gunzburg's reagent would seem to be suffi-

cient for the detection of hydrochloric acid. This is an orange-brown fluid composed of 2 grms. of phloroglucin and 1 gm. of vanillin dissolved in 30 c.c. of absolute alcohol. A few drops of this, gently heated in a porcelain dish with a similar quantity of the fluid obtained by filtering the vomit (or gastric contents withdrawn by stomach-pump or syphon-tube), give a deep crimson crystalline deposit if HCl be present. Lactic acid is detected by it deepening the faint yellow tint of a very dilute solution of ferric chloride. It is now ascertained that during the earliest stage of gastric digestion of an ordinary meal, lactic acid derived by fermentation of the carbohydrates or directly from the ingesta, is alone to be found; later the hydrochloric acid becomes manifest, and at the end of digestion should be the only acid obtainable. Examination of the vomited or withdrawn gastric contents will determine the presence or absence of these acids, and their quantitative analysis may be also approximately estimated. Repeated observations have now shown that the HCl is diminished in amount in pyrexia, anæmia, certain general cachectic states, some gastric neuroses, and in chronic gastric catarrh, whilst it cannot be detected at all in most cases of gastric cancer and atrophic and degenerated states of the mucous membrane. As a means of diagnosis, therefore, the examination of the vomit in this particular becomes of great importance (*see* STOMACH, Diseases of). An increase in the amount of HCl in the stomach may be due to actual hyper-secretion following on the introduction of food, and also to an accumulation of the juice during fasting. Normally there should be no gastric juice in the empty stomach; but in some nervous diseases, such as hysteria and tabes, large quantities of fluid containing a marked excess of HCl may be vomited, independently of food, with epigastric pain and acid eructations. This condition is said to lead to gastro-ectasis and predispose to gastric ulcer. The more frequent cause, however, of 'acidity' is an excess of lactic acid from fermentation of the sugars present, and under these circumstances the HCl is diminished in amount and does not replace the former as it normally should. Butyric, acetic, and other acids of the series may also occur as results of fermentation of the stomach contents. Facts concerning the variation in quality or quantity of the pepsin are wanting, but it would appear to vary with the hydrochloric acid; and the same may be said of the rennet ferment. The efficacy of the gastric juice is impaired by the presence in the stomach of strong alcohol or of bile, which precipitates the pepsin; and an excess of mucus, such as occurs in gastric catarrh, acts prejudicially by preventing the food coming in sufficiently close contact with the secreting surface. During sleep, also, the gastric secretion is diminished.

Notwithstanding that the normal *pancreatic juice* effects active digestive changes in the proteid, fat, and carbohydrate constituents of the food, the results which follow its deficiency in quantity or quality cannot be indicated with precision; possibly its absence may be in part compensated for by the bile and intestinal secretion. It is not to be forgotten that its effective working largely depends on the previous gastric digestion having been properly carried out. There is no doubt but that in many cases, when the pancreatic fluid is completely cut off from the duodenum, the digestion of fats is very considerably interfered with, as shown by the character of the stools, and the rapid emaciation of the patient; but this result is not invariable, and is certainly most marked when the bile is also wanting. In fever the secretion is said to be diminished.

An excessive secretion of *bile* is not clinically recognised except as the result of the administration of certain drugs, but a deficiency or complete absence is of common occurrence in those morbid states associated with obstruction of the bile-ducts, and, to a less degree, in fever. The dyspeptic symptoms directly referable to this state are specially due to the impaired fat digestion, as evidenced by the clayey fœtid stools. Abnormal fermentations, manifested by flatulence, may also take place. The absence of bile further exerts a prejudicial effect on the course of proteid digestion, from the failure to neutralise the acid chyme and consequent precipitation of peptones and arrest of peptic fermentation. The exact changes which ensue are unknown, but there is little doubt that the duodenal digestion of proteids is seriously interfered with by the absence of bile.

So little is known of the action of the *intestinal juice* in health, that nothing can with certainty be affirmed of the part it may play in disease. It is really doubtful which of the alimentary principles it can affect, or whether its action is not limited to effecting further changes in the already partially digested food-stuffs. An excess of the secretion appears to occur, and to form the bulk of the fluid in the diarrhœa of cholera, which may be compared to the salivation and gastric hyper-secretion of certain nerve-states.

In addition to the changes in the ingesta effected by the above-mentioned secretions, there is reason to believe that similar changes of a solvent character may be brought about by the action of *micro-organisms* in the stomach and intestines. Recent observations have demonstrated that numbers of these fungi are normal inhabitants of different parts of the alimentary canal, and that certain species are peculiar to special regions. Originally introduced *ab extrâ*, they propagate enormously, at the same time being subject

to great variation in number, and to some extent in kind, with the food taken. These microbes would seem for the most part to play a minor part in ordinary digestion; although the lactic-acid fermentation of carbohydrates in the stomach, and certain changes in the proteids in the duodenum, resulting in the formation of such bodies as indol, are to be ascribed to their agency. How far, however, such changes are normal and essential is uncertain; but there is no doubt they may be very readily induced and very considerably extended—such as the butyric- and acetic-acid fermentations. In this way may be formed other products of putrefactive decomposition—ptomaines and tox-albumens—often of a poisonous character, and mainly responsible for many remote dyspeptic symptoms; as well as accumulations of such gases as carbonic acid, hydrogen, sulphuretted hydrogen, and marsh-gas, productive of all degrees of flatulence. The exact conditions which permit these abnormal fermentations are not known with certainty. Delay in the propulsion of the gastro-intestinal contents is probably an important factor; and still more so is the proper composition and quantity of the different digestive secretions, by which the activity of many toxic organisms is undoubtedly held in check. Diseases such as cholera and enteric fever, due to specific germs, are not ordinarily accounted as 'disorders of digestion,' though many of their most marked symptoms as well as anatomical lesions are connected with the digestive system.

**4. Deficient Absorption of the Digested Products.**—This may reasonably be supposed to cause indigestion, as it certainly does the subsequent impairment of nutrition. The accumulation in the stomach and intestines of materials which should have been gradually absorbed into the blood or chyle vessels must interfere with the healthy action of the digestive secretions, much in the same way, probably, as the alcoholic fermentation of sugar is arrested in time by the presence of the very products of such fermentation.

Data for estimating the normal rate of absorption from the alimentary mucous membrane of the ordinary results of digestion are very imperfect; and, until they are more clearly ascertained, it is not possible to diagnose with certainty this functional defect, though its existence may often be inferred with much probability, and may suggest modifications in the size if not in the quality of the meals taken.

Conditions upon which an impaired absorption of the digesta may be assumed to depend, are (i.) failure in converting the food to a diffusible state from inefficiency of the secretions; (ii.) impaired peristalsis, whereby the materials are not brought into sufficiently close contact with the mucous mem-

brane; (iii.) deficient circulation of the blood and lymph in the chylopoietic area, and consequent hindering of osmosis; (iv.) disease of the vessel-walls, impairing their permeability; and (v.) degeneration of the epithelium, with the same result.

**SYMPTOMS OF DYSPEPSIA.**—The almost numberless symptoms which indicate the perverted functions above described, and are primarily dependent on morbid structural changes in the organs concerned, may be conveniently grouped into *local* and *remote*. Many so-called dyspeptic symptoms, however, are more properly referable to subsequent perversions of metabolism than to actual digestive imperfections.

The *local* symptoms—those, that is, which are connected directly with the affected structures—are, perversions of sensation; constipation or diarrhœa; vomiting; pyrosis and acidity; hæmatemesis; flatulence; eructation and foul breath; salivation or dry mouth; morbid states of the tongue; abnormal character of the stools. Excepting the first-mentioned, these receive detailed description in the present work under their respective headings.

Ordinarily we are unconscious of the process of digestion, but in disease the function may be accompanied by alterations of sensation varying from a mere sense of weight and discomfort in the abdomen to the severe spasmodic pain of colic. Such, however, are not constant, for very definite indigestion may exist without the patient ever complaining of abdominal sensations. The ingestion of food may be followed by a feeling of abnormal repletion, or of emptiness with craving for food; or there may be heartburn, an ill-defined sense of burning felt in the epigastrium or over the chest or extending to the throat; or positive pain, or tenderness over some tolerably definite area. Sensations as of excessive movements of the bowels, of sinking, or of tightness across the abdomen are of frequent occurrence.

Among the numerous *remote* symptoms are pain in shoulder, back, or limbs; headache—frontal, occipital, and vertical; vertigo and giddiness; muscæ volitantes; tinnitus aurium; cramps in the limbs; muscular weakness; palpitation, cardiac irregularity, flushings, and anginous attacks; cough and singultus; impaired appetite; all degrees of mental perversion, from irritability to apathy and hypochondriasis; drowsiness or insomnia; a peculiar sallow, muddy-looking skin; various cutaneous eruptions, chiefly papular; jaundice; and abnormalities of urine. Mal-digestion may also determine a condition of fever, which may be so severe as to reach the typhoid state and end in coma. Such general perversions of nutrition as wasting and obesity may result from indigestion. Many of these symptoms may be regarded as reflex in causation, such as

distal pains and cough, the afferent nerve-path for which is probably the vagus; others are doubtless to be attributed to actual want of proper materials for the nourishment of the tissues, owing to their improper preparation in the alimentary canal; and others again are possibly toxic in character, due to poisonous substances produced in the course of the perverted digestion.

The extreme diversity of these symptoms is remarkable: there is scarcely a function of the body that may not be implicated in the disturbance of digestion, and contribute its share to the total symptoms of any given case. The degree to which these manifestations may be present is, moreover, most varied: in one patient the malady may be mainly represented by a headache, in another the evidences of illness are most numerous. And, again, the different ways in which these symptoms are associated in different cases are almost as many as the cases themselves. It is impossible, therefore, to attempt any description of a case of indigestion which shall have other than the most limited application; and since the symptoms set forth find their fuller explanation elsewhere in this work, the bare enumeration of them must suffice here. It is important to remember that many of the symptoms mentioned are indicative of disordered digestion are of not infrequent occurrence in the course of maladies quite distinct, or at least primarily so, from digestive diseases: headache, vomiting, cough, palpitation, &c., are illustrations of this. So that, although the recognition of the symptoms be not difficult, care and experience are needful to ascribe them to dyspepsia. But supposing that causes other than indigestion have been excluded, there still remains the task of referring the manifestations of disease which any case may present to their causal perversions in the digestive process: to determine, that is to say, what may be the morbid change which has taken place in the secretions and consequent chemical processes, or the disturbances of motility, or may be the error of diet; and, if possible, to infer beyond these conditions the underlying structural lesions. The intimate interdependence of the various factors of digestion renders the discrimination of the primary fault, from the symptoms present, a matter of exceeding difficulty; and it is this which makes the accurate diagnosis of a case of dyspepsia so uncertain, and its treatment often so empirical. Many of the signs and symptoms, without doubt, indicate with tolerable certainty the region of the alimentary system which is at fault, and may even suggest the nature of the disease; but how far, and in what manner, morbid change in one part of the canal, or at one stage of the digestive process, may determine subsequent changes, and what the exact nature of these may be, and their relation to the symptoms manifested, are data at present

almost unknown. The progressive character of the function of digestion—that is to say, the continuous series of stages, whereby the later ones are dependent on those preceding—renders affections of this system very different in their detection from those of other organs. Alterations in the physical characters of the digestive organs, such as a dilated stomach or an enlarged liver, may usually be ascertained with accuracy, and some symptoms may be reasonably asserted to follow from these conditions, whilst their relation to other morbid manifestations is often of doubtful inference. Modifications in the quantity or quality of the digestive secretions may be demonstrated with certainty, but their connexion with many of the symptoms which may be present is often most obscure. And, again, there may be most persistent and serious disturbance of digestion, with severe discomfort to the patient, and it may be quite uncertain which organ is primarily at fault, and still more doubtful what the real morbid change is. So far as individual symptoms may be referred to definite diseases of the various digestive organs, this is attempted in the articles treating of the diseases of the stomach, intestines, liver, pancreas, &c., which are complementary to this section.

TREATMENT.—The essential basis for the successful treatment of indigestion is the recognition of the cause. Oftener perhaps than may be supposed this is a removable one; in every case it must be well sought for, and corrected if possible. A carefully regulated diet, both as regards ordinary food and special idiosyncrasies, is all-important, and the means from which much good is to be expected, both by way of prevention and cure. To lay down a requisite diet entails a general knowledge of the average composition of food-stuffs and of the changes which they normally undergo in the process of digestion, together with the nature of the influence exerted by various ingredients of the food upon the digestion of the others—*e.g.* ‘the retarding effect of tea and coffee on peptic digestion’ (Roberts). Whether or not any given article of diet should or should not be allowed must depend upon its digestibility in the given case, apart from what may be its value under healthy circumstances, and also upon what harmful by-products of digestion it may give rise to under the diseased conditions which may be present. Exact information on several of these points is not yet available, and at the same time it is to be remembered that articles of food which normally are regarded as of the most digestible and innocent character may at times seriously disagree, whilst most indigestible articles may be taken with impunity. The writer is convinced that, whilst fully recognising the great importance of diet, it is nevertheless the case that not a few

dyspeptics may trace their ailment to a long-continued adhesion to a strict diet which might theoretically fulfil all physiological requirements, and that many cases of indigestion may be considerably benefited by a laxity which might not always be justified on physiological grounds. As useful adjuncts to dietetic treatment are the various artificial partially or wholly digested food-stuffs, such as maltines, peptones, and emulsions of different kinds. Such details of general hygiene as exercise, bathing, occupation—mental and bodily, change of scene and air, require attention scarcely, if at all, secondary to diet. Undoubtedly, much may be done with drugs, both in relieving the symptoms and in treating the conditions on which the symptoms may depend. The latter are met by such means as abstinence from food for periods, with consequent rest to the organs concerned, the requisite nutriment being supplied *per rectum*; by artificially digested aliment, thus helping the digestive juices; and by supplying the elements of the secretions—acids, alkalis, and ferments, when there is reason to suppose they may be deficient. Irregularities of movements of the canal may be remedied by such drugs as strychnine, nux vomica, belladonna, and opium, or more active aperients or astringents. Pain and other sensory disturbances of the stomach or intestines may be relieved by alkalis, bismuth, hydrocyanic acid, morphine, or opium. Among the long list of drugs whose value is assured in different cases of dyspepsia are arsenic, iron, the vegetable bitters, silver, creasote, charcoal, valerian, the hyposulphites, and the various carminatives.

**CONCLUSION.**—In the foregoing remarks no attempt has been made to enter into a detailed description of the various symptoms of disordered digestion, or to do more than indicate very generally the treatment to be followed. Such subjects are left to the diseases treated of in their respective sections. Nor has it been thought desirable in this article to treat the subject from the ill-defined point of view of ‘varieties of dyspepsia.’ Rather it has been sought to bring the matter of indigestion within the limits of an anatomico-physiological basis, since it is only on such lines that the protean symptoms of dyspepsia can be accurately defined. At the same time, whilst for clearness the various causes have been made to assume a somewhat tabular form, it is not intended that the interdependence of these states should be overlooked, or to suggest that one only of the causes mentioned is at work in any given case. The complexity and harmony of our functions alike forbid such a mistake being made. Yet for that mental analysis which the formation of a diagnosis presupposes, some such scheme as the foregoing is essential, no less than for the adoption of a rational treatment.

W. H. ALLCHIN.

**DIGESTIVE ORGANS, Diseases of the.**—The organs comprised in the digestive system have for their function the preparation of the solid and fluid ingesta of the body, so as to fit them for absorption into the blood. Some of the food requires little or even no such preparation; some needs considerable treatment, both physical and chemical. To effect this object it would appear to follow that there should be some receptacle or series of receptacles into which the food may readily be taken, and from which the worthless residue may escape, provided with muscular structures to ensure a movement of its contents. It would further follow that there should be certain organs communicating with the foregoing, whose function it should be to prepare those materials necessary to effect the required chemical changes in the food; and, lastly, that some arrangement should exist to permit of the ready absorption of the digestive materials. Such requirements we find supplied in the alimentary canal, with its terminal apertures, and its continuous muscular coat so arranged as to maintain a progressive advance of the contained food, though with varying degrees of speed—for some lengths, as through the gullet, without any arrest; through others, as the stomach, with considerable delay. Into this canal open numerous glands (mucous, salivary, gastric, intestinal, hepatic, and pancreatic), the secretions of which play each their special part in the conversion of the food to a fluid and diffusible state. From an anatomical, and indeed a genetic, point of view, these glands may be regarded as more or less complicated diverticula of the mucous surface. In order that the food when so treated may gain a ready entrance into the blood, the surface of the canal in contact with the digesting food—mucous membrane—offers various modifications—villi, &c.—to facilitate the process of absorption. Lastly, in beings so complex in structure as man, there is need for some controlling influence to bring the operation of this system of organs into harmony with the actions of other and interdependent systems. Such power of co-ordination is exercised *viâ* the nervous system, sympathetic and cerebro-spinal.

By the expression ‘diseases of the digestive organs’ is meant, departures from the normal structure of the tissues of which these organs are composed.

The constructive tissues of the alimentary organs are:—(1) the Epithelial; (2) the Connective, including the Lymphoid; (3) the Muscular; (4) the Nervous; and (5) a compound texture—the Vascular. Each of these is subject to its own perversions, either alone or in common with others.

**ÆTIOLOGY.**—If we consider diseases to be altered functions dependent on altered structure, the latter being determined by some perversion in the normal stimuli to nutrition,

either hereditary or acquired, we shall at once recognise that the opportunities for abnormal stimulation in the case of the digestive organs are most numerous. Communicating with the external world, and continuously subject to the admission of foreign matter, we have in the character of the ingesta abundant sources of disease. Toxic agents, living and dead, find ready entrance; and excesses in quantity of food, no less than imperfection in its quality, alike serve to produce those departures from the normal structure on which perversions of function depend. Furthermore, the tissues of the alimentary viscera are, equally with those of the body generally, subject to those more obscure hereditary influences which determine irregularities in structure and their sequence. And, finally, arrests in development of organs, not infrequent in those under consideration, complete the list of possible diseases to which the alimentary system is liable.

Nor is this system independent of morbid conditions affecting other organs. So complicated as is the human body, it is impossible that disease should for long be limited to one region. Sooner or later the functions which are acting the one with the other, to constitute the harmonious working of healthy life, will feel the effects of the one that is out of gear, and will respond each in its own manner to the abnormal condition of its environment. A disease primarily located in the nervous system will produce an effect in the working of the nutritive functions, none the less real because the exact lesion cannot as yet be determined. Failures in elimination of the products of tissue-waste, from structural diseases of the excretory glands, must tell back on the organs concerned in the preparation and elaboration of the ingesta; and such conditions constitute a frequent cause of disorders of digestion. The causes may be thus tabulated:—

#### A. Hereditary.

1. Arrests in development of tissues and organs.
2. Abnormal nutritive stimuli, determining new-growths, &c.

#### B. Acquired.

1. Poisons.
2. Imperfections in quantity or quality of normal ingesta.
3. Failure of excretory functions, with consequent circulation of an impure blood, and malnutrition of tissues.
4. Tropic disturbances acting *via* the nervous system.
5. Traumatic.

**VARIETIES OF DISEASE OF THE DIGESTIVE ORGANS.**—There is scarcely any form of diseased structure that is not to be met with in the tissues comprising the digestive organs. Since almost every variety of texture is found in them, and there is so extensive a liability

to the causes of disease, this result is only to be expected.

#### I. Affections of the Vascular State.

Regarded collectively, the organs of digestion present several points worthy of remark in respect to their blood-supply. First, the arrangement of the vessels is such as to ensure a very extensive, and at the same time very direct, supply. The arteries to those alimentary organs situate in the abdomen are almost all primary branches of the aorta; and this, together with the numerous and free anastomoses between them, reduces to a minimum the chance of failure in circulation. Secondly, the blood from the same area is all collected into one large vein—the portal—and after circulating through the liver is carried by one—the hepatic—directly into the inferior vena cava, close to the right auricle. Such an arrangement, whilst considerably reducing the speed of the blood-flow through the hepatic capillaries, offers a double chance—*viz.* in the liver and in the heart—of producing a general state of congestion of the alimentary organs. Thirdly, the existence of such an organ as the spleen, which by its position and structure, as well as its periodic rhythmic contractions, allows of great variation in the amount of blood it contains, will materially affect the extent of vascularity of the digestive organs. And, lastly, the alimentary organs probably undergo, within normal physiological limits, a wider variation in amount of blood than does any other system. The *post-mortem* appearances of the vascularity of the canal, both normal and morbid, are most deceptive, and give little or no indication of what actually exists during life. This is due in great part to the constriction of the vessels after death, and a consequent bloodless state of the tissues.

1. *Hyperæmia.*—*Hyperæmia* is here taken to mean an excess of blood in the arterial side of the capillaries. How far a determination of blood to the alimentary canal may exist, unaccompanied by any change in the tissues, is a matter of doubt: it rarely if ever leads to any recognisable morbid state. In the normal process of digestion this condition obtains, but with it there is an alteration in the glandular epithelia, if in no other tissue-elements. It is conceivable, however, that a vaso-motor paralysis with consequent fluxion may occur, and such may be the case in certain mental states, as indicated by diarrhœa. The majority of circumstances that produce *hyperæmia* do not stop at that point, but bring about a state of catarrh and inflammation, in which the epithelial and connective tissues are also engaged.

Among the digestive glands, the liver undoubtedly manifests states of simple *hyperæmia* without any appreciable changes in the hepatic tissues. Excessive feeding, irritants such as spices and alcohol, hot climates and

malaria, suppressed menstruation, have all been recognised as producing temporary enlargements of the liver from active vascular engorgement, although without doubt these causes if continued lead to structural affections.

2. *Congestion*.—An excess of blood primarily in the venous side of the capillaries, brought about by some impediment to the return of the blood in the veins, has little or no analogy with any normal physiological action. As a condition of disease it is more important and far more common than the preceding.

There are two chief causes leading to its occurrence: (A) It may be part of a general congestion due to obstruction at the right side of the heart from tricuspid dilatation. Owing to the very direct communication of the veins of the chylipoietic viscera and the right auricle, these organs are among the first to experience the effects of the cardiac obstruction. (B) Obstruction through the portal circulation in the liver, either by compression of the portal capillaries by cirrhosis, &c., or by pressure on the portal trunk by enlarged glands, tumours, &c., will directly produce congestion of the gastro-intestinal tract and pancreas. Congestion of the alimentary canal and glands, when due to either of these causes, is in the main progressive in its nature, though occasionally liable to temporary variations in degree.

As a rule, changes which are strictly limited to alterations in the fulness of the vessels are not to be detected with certainty after death; but extreme conditions, especially if associated with any hæmorrhage into the sub-epithelial tissue, may present *post-mortem* appearances often mistaken for irritant poisoning.

3. *Results of Increased Vasculature*.—(a) *Hæmorrhage*. Over-fulness of the capillaries, from whatever cause, is liable to lead to extravasation of blood, either by diapedesis of the corpuscles and transfusion of the fluid part of the blood, or from actual rupture of the vessels. It is much more common and far more extensive in venous congestion than in arterial hyperæmia. It must not be too readily assumed *post mortem* that either of these conditions alone is the cause of the hæmorrhage, since minute ulcers of the mucous membrane communicating with main vessels have been met with. Dependent on the cause and situation, the effused blood may vary in colour from bright red to a coffee-ground appearance. Hæmorrhage may be also due to altered states of the blood, such as purpura and scurvy. (b) *Œdema*. An over-distension of the vessels, especially of the veins, if it be at all persistent, is invariably accompanied by an effusion of serum into the substance of the viscera themselves, and into the alimentary canal, in the latter case producing diarrhœa. (c) Tissues the seat of a chronic congestion in time undergo

certain structural changes as the result of their impaired nutrition, resulting in *atrophy* or *degeneration*; or they may be characterised by the presence of an excessive amount of connective tissue, containing fewer protoplasmic elements than normal, and exhibiting a marked tendency to contract. This *fibroid substitution* may occur throughout the entire digestive system, but is particularly noticeable in the stomach, intestines, liver, and pancreas. (d) Another result of a long-continued congestion is to develop—often to an enormous extent—collateral circulations, especially at the points of communication between the vessels of the portal and systemic areas; e.g. the connexions between the gastric and œsophageal veins around the cardiac orifice, and by the latter with the phrenic, intercostal, and azygos veins, and thence with the inferior vena cava, or the junctions between the hæmorrhoidal veins and branches of the internal iliacs. Considerable compensation is thereby very frequently established, but the over-distension to which the vessels are subject especially favours their rupture.

4. *Anæmia*.—The alimentary viscera, in common with the rest of the body, may share in a general bloodlessness due to excessive loss or extreme malnutrition from wasting disease, &c. A deficiency of blood limited to these organs is not clinically met with.

5. *Infarctions*.—As compared with the brain, spleen, and kidneys, the organs of the alimentary system would appear to be less prone to suffer from emboli and thrombi, or at all events from the effects of these obstructions. A partial exception to this general statement must be made in the case of the liver, which is a frequent seat of abscess determined by the arrest in the portal capillaries of septic particles taken up by the portal radicals in dysentery, &c. Any of the vessels of the liver may be occluded by emboli, or thrombosis following on endarteritis or endophlebitis, but they are conditions of very rare occurrence. The superior mesenteric artery has been known to be blocked by an embolus, with consequent infarction and profuse intestinal hæmorrhage. Minute emboli in the gastric arterioles, or thrombosis from degeneration, atheromatous or hyaline, of these vessels is an undoubted cause of ulcer of the stomach, though not the only one.

II. *Structural Affections*.—1. *Inflammation*.—This term is applied to express those changes which take place in the nutrition of a tissue subsequent to the application of some abnormal stimulus which shall not have been sufficiently powerful to produce destruction. The changes in the structural elements of the textures result partly in the production of some material which is unlike the normal constituents of the part affected, and partly also in certain destructive phenomena. One or other of these phases may predominate, as suppuration and abscess or

ulceration, &c. Certain variations present themselves in the nature of the new-formed material, and also in the general course of the process, constituting forms of inflammation, as simple catarrhal, diphtheritic, phlegmonous, &c. In vascular tissues there are, in addition to the tissue-changes, certain alterations in the circulation in the affected region, commencing with hyperæmia and leading to a variable amount of stasis and œdema.

Inflammation as it affects the alimentary tract offers no exception to this description. It is rare for the muscular tissue to share in the process, which is practically limited to the epithelium, mucosa, and submucosa. The transition, so far as anatomical appearances are concerned, from the normal state of activity of the organs, with their increased vascularity and cloudy appearance of the epithelial cells, to that of simple inflammation or catarrh, is but a step marked by no abrupt line.

Different sections of the entire canal appear to be more prone to certain forms of inflammation than are others. It is unusual for the whole length to be involved, and certain regions, notably the jejunum, are but exceptionally affected. The mouth, pharynx, stomach, lower part of the ileum, and colon are the usual seats. *Catarrhal* inflammation, characterised by intense redness and swelling of the mucous membrane, with an excessive secretion, mucous or serous, and desquamation of the epithelial cells, is of commonest occurrence almost throughout the canal (*see* STOMATITIS; STOMACH, Diseases of; and INTESTINES, Diseases of). When but limited areas are affected and the cause is removed, this condition runs an acute course and tends to recovery; but when the greater part of the canal is involved and the cause is of specific virulence, the effects are more serious. This is the case in cholera, whether of the Asiatic or English type, the anatomical lesion of which is essentially an intestinal catarrh. It is noticeable that the epithelia of this tract are but little prone to manifest a purulent inflammation, as is so characteristic of some other mucous surfaces, such as the nasal, bronchial, and vaginal. *Phlegmonous* inflammation, probably bacterial in origin, corresponding to erysipelas of the skin, and distinguished by the formation of pus in the mucosa and submucosa, represents a more severe inflammatory process, accompanied by a more severe constitutional disturbance. It is of most frequent occurrence in the fauces and tonsils, where it is common (*see* TONSILS, Diseases of), and far more rarely in the stomach, where it constitutes a very serious disease. Under the term *membranous* or *pellicular* are included those forms of inflammation in which the new material assumes the form of a false membrane on or in the mucous surface. This is represented in the mildest degree by aphthæ,

which characterise a special form of stomatitis, and are small patches of coagulated exudation from the blood involving leucocytes and the deeper layers of the stratified oral epithelium. After a day or two's duration they break down and are thrown off, leaving an abrasion or not according to the extent to which the tissues are included in the patch. The more severe forms of inflammation associated with formation of false membrane are termed *croupous* and *diphtheritic*, words which have been extensively misapplied, with much resulting confusion. The former denotes that form of inflammatory product which consists of a coagulated fibrinous exudation effused among the necrosed epithelial cells and into the mucosa, together with many leucocytes and a few red blood-cells; in the latter, the necrosis of the tissue-elements is more extensive and the adherence of the membrane is more intimate. The fauces are by far the most frequent seats of these states, but patches of false membrane are of occasional occurrence in the stomach, and more commonly on the edges of the sacculæ of the large intestine. It is doubtful, however, whether such membranes are diphtheritic in the clinical sense of the term, however closely they may correspond in anatomical characters.

An acute or sub-acute attack of catarrhal inflammation of the stomach or intestines is likely, if the cause persist, to become chronic, the structural features of which are especially an atrophy of the epithelium, with or without much fibroid thickening of the mucosa. The wasting of the epithelium is often very marked, and when the villi also become shrunken the surface of the mucous membrane appears smooth and glazed over large areas. In young children this atrophy appears frequently to follow a single attack of acute intestinal catarrh. Some forms of stomatitis, though persisting a long time, can scarcely be said to be chronic in the sense of leading to permanent structural changes; the utmost that occurs is a thickening of the epithelium, which usually disappears in time. The fibroid overgrowth may affect the stomach or parts of the intestine tolerably uniformly, or not infrequently form polypoid elevations.

Certain peculiarities in the inflammations of special regions, such as the cæcum, colon, and rectum, are fully described elsewhere. *See* CÆCUM, Diseases of; RECTUM, Diseases of; and TYPHLITIS.

The accessory glands (salivary, pancreas, and liver), which genetically are but diverticula of the primitive digestion-tube, essentially consist in the adult state of a glandular epithelium arranged in various ways and supported by a connective-tissue stroma which carries vessels, lymphatics, and nerves. In structure, therefore, they correspond to the mucous membrane of the alimentary canal,

and, like it, they are subject, though much more rarely, to similar inflammatory changes. The communicating ducts of these organs with the mouth and duodenum respectively are lined by a mucous membrane continuous with that of the cavities into which they open. Catarrh of the ducts, usually caused by extension or by the irritation of calculi, may be acute or chronic, and may lead, by the retention of the secretions from the blocked lumen, to inflammation and other changes in the proper gland tissue.

The causes of inflammatory affections of the digestive organs are very numerous. Among those which may be regarded as predisposing are (i.) the exposure of the mucous membrane to injury or irritation from injurious ingesta; (ii.) age, which confers special liability, as witness the frequency of stomatitis and gastro-enteric catarrh in children; (iii.) season, such as extremes of heat and excessive moisture, which are most active in determining epidemics of gastro-intestinal inflammations; (iv.) morbid conditions of the mucous membrane, more especially chronic congestion and degeneration, which favour the development of the catarrhal state. Exciting causes are (i.) the nature of the ingesta, whether mechanically or chemically irritating, corrosive poisons, toxic micro-organisms, ptomaines, and other bodies which may occur in the course of mal-digestion; (ii.) catching cold; (iii.) dentition; (iv.) wounds or malpositions of the bowels, herniæ, &c., impacted fæces; (v.) extension from the peritoneum; (vi.) the irritation of new-growths; (vii.) secondary to many acute febrile states, and some chronic diseases, such as phthisis and diabetes.

Among the chief results of inflammation are:—

(a) *Abscess*.—This may occur in any part of the submucous tissue, in the so-called phlegmonous and pyæmic inflammations, but is of most common occurrence in the gums—gumboil, in the tonsils, and in the liver; often in the latter situation it is the result of inflammation determined by absorption into the mesenteric veins of septic particles from dysenteric ulceration.

(b) *Ulceration*.—The mucous membrane of the alimentary canal is particularly liable to this morbid process. Some preference is exhibited for the different forms of ulcer by certain regions of the canal, and a difference exists in the tendency to perforate the entire thickness of the tube, those of shorter duration frequently producing this result, whilst the chronic ulcers are usually accompanied by a slow formation of indurated connective tissue, which proceeds *pari passu* with the destructive process, and is especially likely to institute adhesions between the canal and adjacent organs. Ulcers are met with in the salivary, hepatic, and pancreatic ducts, very frequently as a sequence of in-

flammation determined by the passage of calculi.

The ulcers which are usually acute in their course are:—(1) Simple or catarrhal. (2) Aphthous. These forms, though they may occur in any part of the mucous membrane, are far more commonly situated on the gums, cheeks, tongue, and palate. (3) Acute specific ulcerations: as diphtheritic and scarlatinal, mainly affecting the fauces; or typhoid, limited to the jejunum and ileum, and originating in the solitary and agminated glands. (4) Dysenteric.

The ulcers that are commonly chronic in their course are:—(1) Gastric. (2) Tubercular, which may occur in any part of the canal, but are usually limited to the same situation as the typhoid. (3) Syphilitic, most common in the mouth, fauces, and rectum. (4) Cancerous. (5) Dysenteric and chronic catarrhal.

(γ) *Sloughing and Gangrene*.—The inflammatory state may be so intense as to lead to molar death of the area affected, with the production of slough. This often follows scarlatinal inflammation of the fauces, and the surface of the large intestine in dysentery is frequently covered by large and numerous sloughs.

Gangrene is almost entirely limited to the mouth in children, when it produces the condition termed noma. The cheeks are usually affected first, the process rapidly involving the gums, jaws, &c. Portions of bowel that have been strangulated readily become gangrenous.

*Post-mortem* softening and destruction of the stomach and intestines is frequently met with, and is due to an actual digestion of the viscera by the gastric juice, which, thus escaping from the stomach, may cause destruction of adjacent organs. It is usually met with when death has occurred during the process of gastric digestion, and is more common in infants, possibly from the greater acidity of the products of digestion.

2. *Hypertrophy*.—A general overgrowth of the normal tissues of the digestive organs is practically unknown. Certain parts may manifest this condition, notably the muscular tissue of parts of the canal above an obstruction. Patches of hypertrophied epithelium are seen in the mouth following on persistent mechanical irritation of broken teeth, &c., or as the result of syphilis. The overgrowth may be limited to the epithelium of the lingual papilla. Considerable hyperplasia of the sub-epithelial connective tissue may be caused by a chronic inflammation of any part of the canal. The liver is described as being occasionally hypertrophied in certain cases of diabetes.

3. *Atrophy*.—The alimentary organs may share in the general atrophy and wasting of old age or inanition. This condition is apt to follow disease of certain parts, especially the epithelia in chronic inflammation, or

may be seen in the thinning and shrinking of the stomach and intestines beyond an obstruction or an artificial anus, or when these organs are permanently dilated. Pressure on the organs, as by tight-lacing, &c., may lead to the same result.

4. *Degenerations.*—Those morbid processes to which the term ‘degeneration’ is applied, and which essentially consist in the conversion of the tissues into materials of a less complex chemical composition than normal, associated with a diminished vital activity, may affect any or all of the structural elements of which the digestive organs are composed. Albuminoid infiltration or cloudy swelling is the invariable accompaniment of inflammation of the epithelial and muscular tissues. Fatty degeneration is a further result of inflammation or of other malnutrition, and has been found in the gastric mucous membrane, as well as in the muscular coat at various parts of the canal. Although not the commonest organs to be so affected, yet not infrequently the intestine and stomach are the seat of lardaceous degeneration, not always limited to the vessels, but affecting also the epithelial, fibrous, and muscular coats. The liver is especially liable to undergo degeneration, both fatty and lardaceous.

Deposition of pigment may be found in the deeper epithelial strata of the mouth and intestines in Addison’s disease, in the gastric and intestinal mucous membrane as the result of changes in effused blood associated with chronic inflammation, and in the liver in certain cases of blood diseases and intermittent fevers. The sulphides of such metals as lead may be deposited in the mucous membrane of mouth or intestines in lines and spots of black or bluish appearance.

5. Changes in or retention of the secretions of the various glands may result in the production of *calculi*—salivary, pancreatic, or biliary.

6. *New-growths.*—There is scarcely any known form of neoplasm which may not be found in some region or another of the alimentary tract.

The new-growths limited to the epithelial coat, or commencing in it, are condylomata, papillomata, and various forms of carcinoma.

In the fibrous tissue occur sarcoma, fibroma, myeloid, adenoid, gumma, enchondroma, and lipoma.

In addition there may be polypi or tumours of the mucous membrane; myxoma; muscular-tissue tumour; cysts; vascular growths, such as nævi and hæmorrhoids; and the infective granulomata, viz. tubercle, lupus, and syphilis.

7. *Traumatic.*—Certain parts of the alimentary tract are, from their position, more liable than others to external injury. Incised and punctured wounds of the mouth, œsophagus, stomach, intestines, and liver are of occasional occurrence, and rupture of the

abdominal viscera is sometimes met with. The ingestion of corrosive substances may produce destruction of certain parts of the canal, and wounds may be determined by foreign bodies, as pins, fish-bones, &c., which have been swallowed.

III. *Malformations and Malpositions.*—1. *Hereditary.*—Of these the most important are hare-lip; cleft palate; macroglossia; fistulous communication between the pharynx and the exterior, or between the gullet and trachea; intestinal cæca; imperforate anus; and herniæ.

2. *Acquired.*—Malformation and malposition of the viscera may follow from disease. Communications between the stomach and intestines, or between different coils of intestine, or between the gall-bladder and the gut, may result from chronic ulceration. Many herniæ are not developed until long after birth, from violent strains, &c.

Stricture of various parts of the canal is frequently associated with the healing of ulcers, and with new-growths. Dilatation of the canal is apt to occur on the proximal, and contraction on the distal side of such strictures. The intestines may be considerably displaced from adhesions following peritonitis. Twists (volvulus), intussusception, internal strangulations, and prolapsus ani, are more or less common affections of the intestines.

IV. *Abnormal Contents.*—*Concretions.*—These are found occasionally in the sacculæ of the large intestine, cæcum, appendix, and, more rarely, stomach and small intestine. They usually are made up of concentric layers of earthy and organic matter, the former being principally phosphates of lime and magnesia. They frequently have as a nucleus some foreign body. Similar bodies have been met with, formed of chalk, magnesia, or oxide of bismuth, which have been swallowed. Much larger masses, mainly composed of densely felted hairs or vegetable husks and fibres, with earthy and fecal matter, are sometimes seen; gasteroliths are generally of this variety (see CALCULI). Foreign bodies, such as pins, bones, fruit-stones, coins, &c., may also lodge in the alimentary canal.

*Parasites.*—The alimentary organs are infested by numerous forms of micro-organisms, belonging for the most part to the vegetable kingdom. The greater number are comprised in the Schizomycetes, or bacteria, but a few, such as the Actinomycetes, found in the mouth and liver, are included in the division Hyphomycetes, or moulds; and as an example of the Blastomycetes, or yeasts, may be mentioned the thrush-fungus, *Saccharomyces albicans*.

These all obtain entrance to the canal from the exterior, chiefly with the food, and the majority give rise to no symptoms of disease provided proper cleanliness be observed. That many propagate and flourish in different parts of the tube is certain, and some appear to take a definite share in converting the food

to a diffusible state, especially in the intestines, and to that extent are true digestive agents. The ferments which set up the lactic-acid change in the stomach are to be considered as normal, whilst those which develop butyric acid are clearly abnormal. The true pathogenic organisms, such as those producing tubercle, typhoid fever, diphtheria, and cholera, develop as they may find their surroundings suitable; but it is also probable that some forms of gastro-intestinal disturbance, such as summer diarrhoea of infants, are due to the activities of bacteria, which produce toxic substances—ptomaines—in the course of putrefactive changes set up by them in the intestinal contents.

A few species of Protozoa have been met with in the intestines, such as *Amœba coli*, *Paramœcium coli*, *Cercomonas intestinalis*, and *Psorospermia*. The other and larger parasites belong to the flat or round worms, and include the various species of *Tœnia* and *Bothriocephalus* among the former, *Ascaris lumbricoïdes*, *Oxyuris vermicularis*, *Trichocephalus dispar*, and *Ankylostoma duodenale* among the latter. See ENTOMOZOA.

*Gases.*—The gases normally occurring in the stomach or intestines, whether they be swallowed with the food or formed during fermentation in the canal, are often much increased in amount, especially carbonic acid, sulphuretted hydrogen, and marsh gas, the last named being inflammable, and occasionally eructated in considerable quantity.

W. H. ALLCHIN.

### DILATATION (*dilato*, I enlarge).

*ÆTIOLOGY.*—Dilatation of any of the cavities, tubes, or orifices of the body may either result from increased pressure from within, or from diminution in the resisting power of the walls of the tubes or cavities. These two causes are frequently combined, and, indeed, the latter is often the result of a long continuance of the former. Increased pressure from within may be due either to increased secretion of the normal contents of the cavity, or to some other effusion into it. This is the usual cause of dilatation of the closed cavities of the body; we have examples in the ventricles of the brain, the pericardium, the synovial cavities, the bursæ, the follicles of the thyroid body in cystic goitre, and the Graafian vesicles in some forms of ovarian dropsy. In the various tubes of the body, increased pressure from within may arise from obstruction, and the consequent accumulation behind the seat of obstruction of the substances which it is the function of the tubes to transmit.

*VARIETIES AND CHARACTERS.*—1. *Cystic dilatation.*—In tubes which begin by blind extremities the result of dilatation is generally the formation of a cyst, and this is the usual mode of origin of the large class of *retention-cysts*, or *cystic dilatation*. We have ex-

amples in the sebaceous cysts, in the cysts of mucous membranes, due to the ducts of the mucous glands becoming obstructed by the products of catarrhal inflammation, in cysts of the kidney formed by dilatations of the Malpighian capsules and uniriferous tubules, and in dilatations of the gall-bladder, and of the pelvis of the kidney.

2. *Uniform or cylindrical dilatation.*—In tubes not beginning by blind extremities, the effect of the obstruction is usually to produce a *uniform* or *cylindrical*, and not a cystic dilatation; though sometimes one part of the wall will yield, and so cause a diverticulum or sacculus. These uniform and cylindrical dilatations may occur in all the tubes of the body. They are met with in the œsophagus and all parts of the digestive canal, in the heart, veins, bladder, ureters, bile-ducts, &c. This form of dilatation may be attended either with thickening and hypertrophy, or with thinning and atrophy of the walls. Usually when the tubes are in the main muscular, hypertrophy occurs, from increased exercise of the muscular fibres in their efforts to overcome the obstruction; but when the walls are mainly fibrous or elastic, they generally become atrophied and thinned.

3. *Compensatory or collateral dilatation.* Another form of dilatation from increased internal pressure may be termed *compensatory* or *collateral* dilatation; it is produced by the tubes having to transmit an increased quantity of fluid in consequence of the obstruction of other channels. Besides the blood-vessels, we may meet with examples of compensatory dilatation in one ureter when the other is blocked, and in the bronchial tubes and other parts. Resembling this form in its mode of origin is the dilatation caused by tubes having to transmit substances of too large a calibre, as, for example, in the passage of calculi down the gall-duct and ureters.

4. *Dilatation from changes in the walls.* The last class of dilatations consists of those due to diminished power of resistance in the walls of the tubes or cavities. The most important examples of this class occur in the circulatory and respiratory systems: in the heart from fatty degeneration; in the arteries from atheromatous changes. In the respiratory organs it occurs both in the bronchial tubes and in the air-cells. Here, however, the loss of resisting power is itself usually caused by prolonged increased pressure from within; which in the air-cells, as their walls are elastic and not muscular, rapidly causes atrophy, and subsequent dilatation.

W. CAYLEY.

### DILUENTS (*diluo*, I wash or dilute).

*DEFINITION.*—Remedies which increase the proportion of fluid in the blood.

*ENUMERATION.*—Water is the only real diluent. It is given for this purpose in various

forms—soups, *tisanes*, barley water, toast and water, milk, lemonade, aerated waters, &c.—to quench thirst, and increase secretion.

USES.—Diluents are employed to lessen thirst, as in fever and diabetes, and to remove the products of tissue-waste. As the thirst may depend upon local dryness of the throat, as well as upon general want of fluid in the system, the power of water to quench thirst may be greatly increased by adding to it a little vegetable or mineral acid, or some aromatic, such as lemon or orange peel, which will stimulate the flow of saliva, and thus tend to keep the mouth moist after the liquid itself has been swallowed. The thirst-quenching power of water is also aided by the addition of mucilaginous substances, such as oatmeal, or linseed tea, which, leaving a mucilaginous coat on the inside of the mouth and pharynx, retard evaporation, and thus lessen the dryness of the mucous membrane. The free use of water, and especially drinking hot water on rising in the morning, or on going to bed at night, and between meals, is useful in gout, chronic rheumatism, and biliary lithiasis, lessening or preventing the occurrence of acute attacks.

T. LAUDER BRUNTON.

**DIPHThERIA** (*διφθέρη*, a skin).—  
SYNON. : Fr. *Diphthérite*; *Diphthérie*; Ger. *Diphtheritis*; *Diphtherie*.

DEFINITION.—An acute, specific, contagious and infectious, and often epidemic, general disease; accompanied by pyrexia and great weakness; having as its local manifestation inflammation of various mucous membranes, particularly those of the throat and larynx, and the formation upon them, or upon external wounds, of ulcers covered by a fibrinous false membrane; and often followed by paralysis of varied distribution.

HISTORY.—From the writings of the most ancient physicians, it is evident that the disease we know as diphtheria existed in the earliest ages, and then had main features differing little, if at all, from those with which it presents itself to us now. Hippocrates, Aretæus, Galen, Celsus, and Aëtius, have all left fragmentary accounts of a disease prevalent in their time, which serve for its identification with diphtheria. From the sixteenth century onwards, since which time medical observation has been more fully recorded, we have reliable descriptions of epidemic diphtheria occurring at times in various parts of Europe, which leave no doubt as to the nature of the disease, and show that essentially it had not changed for centuries. Bretonneau, in a work published in 1826, gave an account of his experience of the disease, beginning with an epidemic in Tours in 1818; and from this description dates the copious modern literature upon the subject. Bretonneau, too, gave the modern name to the disease, by calling it *diphthérite*, and later *diphthérie*, in allusion to the production of

membranes or skins—a special character of the malady. The most severe outbreak of diphtheria which has occurred in England was that which attained its height about the year 1858. But while later epidemics may not have been so severe as this, their occurrence has become more frequent, and, as will be discussed in the section on Pathology, the disease is now endemic in our large towns. In the article upon CROUP, the writer has given his reasons for believing that at least a large majority of cases classed under this head are really true diphtheria having its primary seat in the larynx. But membranous croup and diphtheria are even yet considered by some physicians as distinct diseases, and in former times this view was much more prevalent. Consequently, many of the outbreaks of 'croup' in Scotland and England must be considered as epidemics of diphtheria. It is noteworthy, too, that the recent returns of the Registrar-General show an increase in the number of cases of diphtheria and a decrease in those of croup, doubtless from the recognition of most cases of the latter disease as examples of laryngeal diphtheria.

INCUBATION.—After exposure to the poison of diphtheria a certain interval elapses before definite phenomena of the disease appear, whether these be of the nature of general symptoms or the beginnings of the local lesion. This period of incubation varies greatly. It is much shorter after direct inoculation than when the poison is taken into the system by other channels. When animals are inoculated with diphtheritic poison, signs of the disease may appear in about twelve hours, or may be delayed as long as three days. In the human subject such inoculation occasionally takes place, as when diphtheritic membrane comes in contact with an open wound in another patient, or when instruments which have been used for an operation upon a diphtheritic subject have not been thoroughly cleansed and disinfected before being used for other purposes. In such cases the period of incubation resembles that seen in the experiments upon animals, but may be prolonged to four days. When, however, the poison is received in other and more indirect ways, the incubation time is much more variable, and probably its ordinary limits are from two to eight days. Yet certainly the lower limit is frequently anticipated, for there is no reason to doubt the accuracy of many published cases, in which the disease began a few hours only after exposure to infection. Cases are on record, too, where the incubation seemed to have been much longer, but these are more doubtful. Not only may it be suggested that a second exposure had occurred, but it is likely that, where this can be disproved, the poison was not received into the body at the time of exposure, but was held by fomites

until a period much nearer to the outbreak, when the patient was in a more favourable state to receive the disease.

A difficulty in determining the period of incubation is caused by the invasion of the disease being not infrequently insidious. During the incubation, while there may be no symptoms at all, there may be mere indefinite feelings of malaise, not to be distinguished from the early symptoms of invasion in a mild attack.

There is reason to believe that the more intense the poison, or the more liable the patient, the shorter is the period of incubation.

**SYMPTOMS.**—*Invasion.*—According to the severity of the disease in its clinical aspects, three separate types of diphtheria may be distinguished—the benign, the ordinary, and the malignant. These are not natural orders, but relative terms. Numerous cases occur which throughout their course may be classified as belonging to one or other of these groups. Yet, on the other hand, instances are also numerous which show a transition from one to the other group, which, beginning, for example, after the benign type, afterwards show the most serious symptoms or sequelæ of the disease; or which, presenting only ordinary symptoms at the onset, rapidly assume the features of the malignant type.

1. It will be convenient to describe in the first place the symptoms of the disease as it is *ordinarily* met with.

In such cases, after a period of incubation, the patient, as a rule gradually, but often almost suddenly, feels ill. He has wandering aches and pains, disinclination for exertion, slight headache, chilliness, loss of appetite, nausea—and rarely even vomiting, thirst, and the general discomfort of a febrile condition. The temperature of the body is raised, but not to a great degree—in most cases, at the onset, to not more than 100° or 101° F. At this time, however, the local symptoms of the disease appear in the form of soreness and tenderness of the throat, and slight enlargement of the glands at the angles of the jaws. The fauces, tonsils, soft palate, and pharynx are swollen, and show a diffuse dusky redness. The pulse and the respiration are hurried, in accordance with the general febrile state. The urine presents the usual febrile condition.

The symptoms rapidly increase in severity. The bodily weakness becomes extreme, and anæmia soon presents itself. The glands, not only those at the angles of the jaws, but their lymphatic connexions also, become greatly swollen, painful, and tender; and their covering of skin may be reddened. The pulse is frequent, feeble, and of low arterial tension; the respirations are more hurried. The local disorder now becomes characteristic. The tonsils themselves assume a paler aspect, but are surrounded by the reddened mucous

membrane. Soon a white haziness appears in patches on the tonsils, the soft palate, or the pharynx. While the swelling of the parts already mentioned greatly increases, the haziness becomes more pronounced, until in disseminated patches a distinct false membrane is seen, slightly raised from the surrounding parts, yellowish-white in colour, ragged in outline, and surrounded by a zone of congestion distinguishable even from the general redness of the neighbourhood. At first the membrane can be detached from the underlying parts; and when removed it leaves an intensely red surface behind. But very soon it becomes more adherent, and its removal is only attained by laceration of the mucous membrane and the exposure of a bleeding ulcerated surface, on which a new layer of false membrane is formed in a short time. The membrane spreads, and may cover the whole of the fauces and pharynx. When this occurs there is usually so much swelling of the parts that scarcely any opening of the fauces can be seen. Further, the aspect of the membrane changes. From being yellowish-white, thin, and delicate, it becomes thicker, of a brownish tint, firm and leathery in texture. The difference in colour is due to admixture with decomposed blood-pigment, the entanglement of atmospheric particles, and drying of the exudation. Signs of coryza are present, and from the nostrils a thin acrid discharge issues.

The tongue is dry, coated with a white or brownish fur, and red at the tip. Appetite is entirely lost, and as a rare symptom there may be vomiting. Swallowing is difficult and painful. The bowels are, as a rule, constipated. The temperature becomes higher, but does not attain the extreme degree seen in many other fevers. Its ordinary height is between 102° and 103° F. The examination of the chest at this time, provided the case is uncomplicated, reveals either nothing at all, or only the rhonchi and râles of bronchial congestion. The urine is still febrile, and in a large number of cases contains albumen. Slight delirium may occur, but is not a frequent symptom in the ordinary type.

When such cases tend to a favourable issue, the duration of the disease is variable. Even after such a moderately severe form as that just described, the symptoms may begin to decline at about the fourth day; the patches of false membrane, after separating, cease to re-form; and the patient rapidly resumes his ordinary health. Usually, however, both the general and the local symptoms are prolonged for a much longer period, say up to the twelfth or fourteenth day, when slow convalescence begins.

Such is a description of the form in which diphtheria ordinarily presents itself, without any of the numerous complications which may occur. Many of the symptoms, how-

ever, require a more detailed description, and this will be given below.

2. The *benign* form is so mild that a considerable number of patients pass through it with so little feeling of illness that they consider it unnecessary to consult a medical man at all. There can be no doubt that such ambulant cases are important factors in spreading the disease. The patient suffers from but slight malaise and weakness, with loss of appetite and slight fever. The urine is usually not albuminous. No complaint whatever may be made of soreness of throat; and for this reason the nature of the complaint is frequently overlooked, even by medical men. Generally, however, there is some soreness in swallowing, and a little enlargement of the glands at the angles of the jaws. On examination, a few white patches of false membrane, easily detached, will be seen on the tonsils, rarely on the soft palate or pharynx. Rarely, with only mild general symptoms, very extensive deposit may be seen in the throat. In a few days the patches disappear, either by being coughed out or by gradual dissolution; no more form; the symptoms, slight as they were, decline; and the patient rapidly resumes his usual health. During the whole period of the disease it is possible for the patient to walk about, and even attend to his usual duties. But this is very undesirable, not only because such cases are as capable of spreading infection as more severe ones, but because, however slight may be the condition at the onset, at any time more serious symptoms may arise, and in this, the benign, form there is no exemption from the most dangerous complications and sequelæ of the disease, such as spread of the membrane to the larynx, cardiac failure, and paralysis.

3. The *malignant* form of diphtheria is characterised by severity rather of the general symptoms than of the local lesions. Commonly, from the first the symptoms are severe, though the early features of the case may be those of the ordinary or even of the benign form. There is extreme prostration; the pulse is rapid, feeble, and of low tension; and the respirations are hurried and shallow. The skin is dry, pungent to the touch, and of a generally dusky hue. The tongue is dry and brown. Very soon the 'typhoid' state develops, and there may be sometimes a muttering delirium, though in most cases this is absent. A hæmorrhagic diathesis is a frequent phenomenon in this condition, and is shown by the occurrence of hæmorrhages from various mucous membranes, or beneath the conjunctiva, and by the appearance of a purpuric rash on the skin. The temperature may be highly febrile, or not unduly raised. The urine is albuminous. While the symptoms of the throat-lesion are not very evident, yet its signs are characteristic. The false membrane is soft, pultaceous, and very dark—

sometimes black, in colour. It is often extensive; and the tissues around are sloughing or gangrenous. A foul smell comes from the putrifying mass at the back of the throat. In most cases, too, the false membrane has spread to the nose; and a sanious discharge, also of foul smell, issues from the nostrils, and by its irritation excoriates the skin around with which it comes into contact. The glands of the neck are always much enlarged and inflamed. Such a condition in most cases ends fatally in a short time.

This general description of the three types of diphtheria requires to be supplemented by a detailed account of some of the symptoms.

*Formation and Spread of the False Membrane.*—The presence of the false membrane is the characteristic feature of diphtheria, and that from which it derives its name. It is the special local manifestation of the disease. But, as will be clear from the descriptions given, in diphtheria we have to deal with general symptoms which, in point of severity, may have no relation to the extent of the local lesion. In the benign form we may sometimes find the general symptoms very slight, or practically absent, while a large quantity of membrane may be seen in the throat. In the malignant form we may have the most severe general symptoms when the local phenomena, severe it may be, are not so prominent as the signs of general disease. The question then arises whether we may occasionally meet with general symptoms of diphtheritic fever, not only without signs of any local lesion, but without the appearance of any false membrane, and with merely congestion and swelling of the fauces, having no specialised character. It is in the experience of clinicians that this occurs, but certainly very rarely. It is possible that, in the course of an epidemic of diphtheria, instances of the benign form may be met with without more local lesion than the early congestion described; yet in such cases a slight formation of false membrane may easily be overlooked. Because of the existence of such a condition, Virchow originally described a catarrhal form of diphtheria, in which no membrane at all was formed. But it is beyond doubt that the poison of diphtheria may act so powerfully upon the system as to, in extremely rare cases, kill the patient before the local lesion has time to develop. It is only such cases as these which can without fear of error be used for argument; but they have been recorded by such competent observers that it must be admitted that diphtheria may at times occur without any specialised local lesion.

In by far the majority of cases, however, false membrane does appear. Generally it occurs first on some part of the throat—either on the tonsils, soft palate, or the back of the pharynx. Usually, too, it is seen in one or more spots simultaneously on both sides, and

most commonly on the tonsils. Yet, occasionally, at an early period but one side may be attacked, but soon, however, an affection of the opposite side follows. The membrane can, at quite its early appearance, be detached with but slight difficulty, leaving a very red or hæmorrhagic surface behind. But very soon its connexions to the subjacent parts become much firmer; it can be removed only by some force, and leaves behind a rough, bleeding, and ulcerated surface. In all but extremely slight cases, a new formation of membrane then occurs; and this may be repeated many times if the disease continues. The detachment of membrane also takes place naturally, not only at the termination of the case, but during its height, new membranes being again formed. In this way, the patient may expel from the mouth, usually by coughing, large quantities of the false membrane, in small or large shreds. Where the larynx and trachea are attacked, complete casts of these cavities may be thus expectorated; and in still more serious cases even moulds of the smaller bronchi are occasionally coughed up.

In the early stages, the membrane appears as a thin whitish deposit, which rapidly thickens. The colour, too, soon changes, passing through stages of grey, greyish-yellow, yellow, brown, and even black. Its consistence increases, becoming in most cases very firm, and resembling shreds of kid-leather. In the malignant form, the membrane becomes softened, and even pultaceous. Its colour then is still darker, and the membrane becomes mixed with blood or the products of its decomposition.

The isolated patches in which the membrane first appears soon spread and amalgamate, until the whole of the throat, as seen on opening the mouth, is entirely covered. But the affection spreads farther. One of the most dangerous complications of diphtheria, and also one of the most frequent, is the spread of the membrane to the larynx. This is more frequent in children; and, while dangerous in adults, is still more so in children, because of the greater ease with which it diminishes the lumen of the glottis. The signs by which the complication may be diagnosed are the following. The patient feels soreness in the larynx, and is greatly troubled by cough. The breathing becomes first wheezy, then stridulous, and always more hurried than before. The cough is harsh; the voice is hoarse and husky, and finally lost. The patient, if a child, clutches at the throat as if to remove an obstruction. Soon the narrowing of the larynx interferes greatly with the entrance of air into the lungs. All the extraordinary muscles of inspiration are brought into action. The lower ribs cease to move outwards, and later on are depressed at each inspiration. The supra-clavicular spaces are similarly de-

pressed. These signs are more obvious in children: in very young subjects, and especially in those affected by rickets, the whole chest-wall may be depressed as each breath is drawn. Signs of cyanosis may now be observed in blueness of the lips and cheeks; but more commonly the face is pallid. The pulse is very rapid. The temperature is no more raised than it was before, and may indeed be only slightly above the normal. The forehead, and even the whole body, becomes covered with a cold clammy sweat. If unrelieved by operation, this condition soon ends in death, occasionally preceded, in young subjects, by convulsions.

The opinions of observers of great experience vary as to the period of the disease at which extension of membrane from the pharynx to the trachea is most likely to occur. Sir William Jenner stated that he had never known this complication commence after the expiration of the first week of the disease. Oertel, on the other hand, speaks of its occurrence as late as the thirteenth day; and Hensch saw it begin fourteen days after the commencement of the primary disease. Sir William Jenner's statement, however, is correct for the majority of cases; and we may place the usual time of appearance of secondary laryngeal symptoms at three to six days after the onset of the diphtheria. It is rather in the mild and in the ordinary forms than in the malignant that this complication may be looked for. Yet its appearance is a sign of extreme danger; most of the deaths from diphtheria are due to this cause. Sir William Jenner again states that he had seen death occur twelve hours after the onset of laryngeal symptoms, and had never known it delayed more than five days; and his experience agreed with that of Bretonneau.

The membrane frequently spreads to the nares also. This is almost invariably the case in the malignant, but occurs, too, in the ordinary form. The symptoms of the complication are snoring or snuffling respiration, and the discharge of an acrid fluid from the nostrils, which excoriates the surrounding skin. The excoriations may in their turn become covered by diphtheritic membrane when the disease is severe. Shreds of membrane, too, may be discharged from the nostrils. Epistaxis is of frequent occurrence. Sometimes, as stated in the account of malignant diphtheria, this is due to the general tendency to hæmorrhage found in septic diseases, but it is also a sign of invasion of the nasal mucous membrane. From the nose the lacrymal ducts, and even the conjunctivæ, may be infected, leading occasionally to destruction of the eyeball.

Spreading from the throat, the membranous formation easily reaches the upper pharynx, and by way of this proceeds to the middle ear. Great pain and sense of distension are thereby produced, and severe *otitis media*

with destruction of the parts, or even *otitis interna* and *externa*, and necrosis of the bone, may result.

The œsophagus, too, may be affected in the whole of its length, and even the stomach and intestines, as will be mentioned in the pathological description.

Sometimes false membrane may appear in various parts of the mouth, probably by the infection of abrasions of surface.

In most cases, as above described, the membrane makes its first appearance in the throat. Yet numerous cases are now on record in which it has first been seen elsewhere.

The primary laryngeal form of the disease is well recognised, and has been known by the name of Diphtheritic Croup. The general symptoms of the disease are then the same as in the ordinary form, but signs of the trouble in the larynx occur early and before any affection of the pharynx can be detected. With the laryngoscope, if the patient will allow of it being used, false membrane, having the ordinary appearance, can be seen covering the posterior surface of the epiglottis, the whole of the interior of the larynx, and even of the trachea. The affection may remain localised in the larynx until death, or may extend thence to the pharynx and other parts.

A primary nasal form is rare, but sometimes met with. Here the coryzal symptoms and the muco-purulent or sanious discharge from the nostrils occur early in the disease; and, when the affection is advanced, false membrane may be seen near the anterior nares. From the posterior nares the lesion may spread to the pharynx, as in the laryngeal form. Such cases are often overlooked in their early stages, because of the obscure position of the characteristic membrane. They are generally severe in character.

External wounds or abrasions may be secondarily infected and covered by false membrane in the course of the ordinary disease. But, on the other hand, there happen cases in which not only has the first local appearance of the disease been seen in an external wound, but the inoculation of such a wound has been the means of infecting the general system. Thus diphtheria has originated from the use of an infected instrument in the operation of circumcision, diphtheritic membrane first developing on the wound. Dr. Hill has recently described cases in which the primary lesion was on the perinæum. Dr. Braxton Hicks and others have also described cases where the first appearance of the false membrane was on some part of the female genital organs, doubtless as the result of accidental inoculation.

*Affection of the Glands.*—The glands beneath the jaw are swollen and tender in all but very exceptional cases of diphtheria. In

most they are so large as to be easily seen; in nearly all they can be felt. But in by far the larger majority of cases the swelling of the glands is a very marked feature. In severe cases, too, it is not only the glands beneath the jaw, but also all those of the neck, on both sides, though the affection of one side may predominate. The skin covering them is swollen, reddened, and œdematous. Sometimes, too, the tissue lying between the glands is greatly inflamed; and in a few cases a brawny hardness, extending from the jaw to the clavicle and involving apparently all the tissues of the neck, an *angina Ludovici*, has been observed. Rarely, the glandular inflammation may proceed to suppuration, causing a large and formidable abscess. The affection of the glands and surrounding tissue is more marked in the severe, and especially in the malignant forms.

*Condition of the Urine.*—The urine in diphtheria resembles in its general characters that of other febrile diseases, though the features are less marked than in other affections. It is diminished in quantity, high-coloured, and deposits urates and uric acid. Sometimes, too, it may appear but little changed. But a special feature of the disease is the occurrence of albuminuria, as first pointed out by Dr. Wade of Birmingham, in the *Midland Quarterly Journal of Medicine*, 1857. This appearance is very frequent, and is found, according to statistics, in one-half or even two-thirds of the total number of cases. The amount of albumen may be only slight, or, on the other hand, very great; and it may disappear from day to day, to again return. With it may be found in the urine hyaline or epithelial casts, but only very rarely blood, and the occurrence of albuminuria is in only extremely exceptional cases accompanied by anasarca or followed by any uræmic symptoms. Whether albuminuria is present or not, the daily excretion of urea is normal, or increased. It differs markedly from the albuminuria of scarlet fever, in making its appearance nearly always during the acute course of the disease: very seldom at the time of convalescence. In most cases it appears on the third or fourth day. Sanné, amongst others, has made extended investigations into this complication. He examined, in reference to albuminuria, 224 cases; and found that it appeared on the first day in three, on the second day in ten, on the third and also on the fourth day in thirty, on the fifth day in twenty-two. After the fifteenth day albuminuria occurred only once for the first time. As a general rule, the greater the quantity of albumen in the urine, and the earlier its appearance, the more severe is the case; but the mere presence of albuminuria does not affect the prognosis of the diphtheria. In most cases the albumen disappears during convalescence; though, as the writer can confirm, it may continue in the urine for months in moderate amount, and

unaccompanied by other symptoms, beyond slight weakness and anæmia. On the other hand, the writer has reason to believe that in exceptional cases chronic nephritis may have its origin in an attack of diphtheria.

*Temperature.*—The temperature in diphtheria has no definite course. It rises suddenly early in the disease, and as a rule continues, with morning remissions, until the beginning of convalescence, when it declines gradually. The average temperature at the height of the attack is from 102° to 103°, and very rarely does it exceed 104° F. It may become raised above the average limit by the advent of complications, such as broncho-pneumonia or suppuration in the neck; but, with these exceptions, the height of the temperature is no certain guide to the severity of the general disease or to the extent of the local lesion. In cases of prolonged diphtheria, such as will be noted below, after remissions or even intermissions of the raised temperature, renewed attacks of pyrexia are met with, generally associated with increase of the general symptoms.

*The Pulse and Heart.*—The pulse in diphtheria is throughout of an asthenic character, short, ill-sustained, and of low tension. In the majority of cases it is frequent, above the degree to be expected from the fever. Dr. Sidney Phillips, in the *British Medical Journal*, 1890, i. p. 960, has analysed 100 cases of diphtheria with reference to the states of the circulation which may occur. In three per cent. of his cases the pulse was unduly slow, and these instances were characterised by vomiting and by a fatal issue. He concludes that a very rapid pulse, also a very dangerous symptom, may occur without any other phenomenon, but may be accompanied by vomiting and extreme drowsiness. Irregularity both in the rhythm and the force of the pulse is not uncommon and not unfavourable. The heart-sounds are feeble, and the first sound short. Disturbances of the intervals between the sounds are, in the opinion of the writer, of great importance. A rapid sequence of the second sound upon the first, but especially 'spacing' of the sounds, as heard at the apex of the heart—that is, an equalling of the intervals between the first and second, and the second and succeeding first sound respectively—are of most serious import, and indicate a liability to sudden cardiac failure, the most dangerous complication of diphtheria. These alterations in the sounds of the heart may be detected both at the height of the fever and during convalescence, and are equally important at either time. Acute dilatation of the heart, usually of the right ventricle, sometimes of the left, is not infrequent in diphtheria. It may be accompanied by a systolic murmur, heard at the apex or over the area of the pulmonary artery. But such a murmur is not due to endocarditis. Bou-

chard and Labadie-Lagrave have maintained that endocarditis is a frequent complication of diphtheria, but their opinion has been supported by no other observers. The cardiac dilatation does not occasion dropsy, as it does in most other conditions, but the weakness of the heart's impulse is the cause of the thrombosis of the large veins which sometimes, though rarely, occurs.

*Rash.*—A certain degree of efflorescence on the skin is not uncommon in unmixed cases of diphtheria, and especially in the severe variety. It is usually seen about the neck and the upper part of the chest. It is a diffuse redness, not punctate, and not papular in the slightest degree. This is not a specific rash, and must be carefully distinguished from that of scarlet fever. To the writer, it has appeared to be somewhat darker in colour than the rash of scarlet fever. In the malignant forms purpuric spots of different sizes may be observed, scattered over the whole surface of the body in great numbers.

*COMPLICATIONS AND SEQUELÆ.*—Many of the complications have already been described in the foregoing account of the disorder, and such will be here only enumerated.

1. Extension of the false membrane to the larynx and lower air-passages, to the nose, ear, and eye.

2. Formation of false membrane on external wounds and abrasions.

3. Extensive ulceration, and even gangrene, of the tissues of the throat. Hænoch mentions perforation of the palate as an occasional result.

4. Great inflammation in the neck, and rarely suppuration.

5. Albuminuria.

6. Suppression of urine, and uræmia. This has been described by Oertel and by a few other observers, but its occurrence is contrary to general experience; and, as Dr. Hilton Fagge has remarked, it is probable that scarlet fever has been overlooked in such cases.

7. Dilatation of the heart.

8. Cardiac failure, syncope, and sudden death. This complication is the most dangerous which can occur in diphtheria, and may come on at any period of the disease, and even during convalescence. It is preceded usually by a very frequent, sometimes by a slow, pulse, but its special warning is an alteration in the sounds of the heart, as described above. The cardiac failure may in some cases show itself by a gradual failure of the circulation, but usually by sudden syncope, which is nearly always fatal. The most distressing cases in which this occurs are those where the patient, some time after the decline of pyrexia, is in full convalescence, or even in apparently good health, yet suddenly faints and almost instantly dies. No patient is absolutely safe from this fatal

mishap until at least six weeks after the apparent end of the disease.

9. Hæmorrhages. These may occur, not only from the ulcerated mucous membranes, but also from any mucous surface. They may be so copious as to seriously weaken the patient.

10. Thrombosis of veins.

11. Affections of the bronchi and lungs. General bronchitis may be met with in diphtheria before the larynx is attacked, and may be followed by extensive broncho-pneumonia. Both these complications are, however, more frequent when the air-passages become involved in the special diphtheritic inflammation. Collapse of lung, emphysema, and hæmorrhage into the tissues of the lung are also met with at times. Their special symptoms are added to those of the original complaint, and need not be here detailed.

12. Paralysis. Though paralysis may follow other febrile disorders, yet it is so frequently an association of diphtheria as to form a characteristic feature of the disease. The paralysis, as statistics show, varies in its frequency in different epidemics. Cadet de Gassicourt found that it occurred in 128 cases out of 937. Dr. Gowers states that its frequency has been reported as from 8 to 66 per cent., and that probably one-fourth of the cases which do not die from the primary disease suffer from paralysis. The paralysis as a rule appears about two or three weeks after the decline of the pyrexia, but it may occur during the height of the disease, even as early as the second day (Sanné), and it may be delayed until the fourth or fifth week from the attack. As Landouzy has shown, the older the patient the more liable he is to this sequela. It is more common after slight cases of diphtheria, but its onset is earlier in the severe forms.

The first part to be affected by the paralysis is the soft palate. The patient then speaks with a nasal voice, and is unable to swallow fluids, since the immobile palate no longer closes the entrance to the posterior nares, and so fluids regurgitate through the nose. The palate hangs motionless during respiration and phonation, and is insensitive to touch. Occasionally, and for a time only, one side of the palate remains unaffected, and then the uvula is drawn to one side and the curves of the palatal edges are unequal. In rare cases the inability to swallow extends to solids also, from paralysis of the muscles of the pharynx.

The next most common paralysis is that of the eye. The most obvious effect of this paralysis, and that which most readily attracts the attention of the patient's friends, is an external strabismus from paralysis of the internal rectus muscle. But this is not the most common result. More frequently we meet with a paralysis of the ciliary muscle, usually in both eyes, which has as its effect

a loss of the power of accommodation. Unless the patient has previously been myopic, he is now unable to adjust his eye for near objects, as, for instance, in the act of reading, while vision for distant objects remains unaltered. The pupil, too, is sluggish in contracting to light. Other muscles of the eyeball may suffer, so that various forms of squint are met with, and sometimes ptosis; while, in exceptional cases, one or even both eyes have become absolutely motionless from paralysis of all their muscles. Concentric contraction of the fields of vision has been described.

Other organs of sense suffer but rarely, but Dr. Gowers states that he has met with loss of taste, and loss of smell without loss of taste.

The limbs next suffer from the paralysis, and usually the lower before the upper limbs. The paralysis is generally preceded by tingling feelings, sense of 'pins and needles,' or actual pain, in the parts about to be attacked. Then gradually and slowly the paralysis sets in. It is but rarely complete, but always sufficient to render the muscles practically useless. The muscles are flaccid and soon begin to atrophy. The knee-jerks are lost; but this phenomenon may be met with, as Dr. Buzzard and Dr. Hadden have shown, early in the primary disease; and Dr. Angel Money has found that there may be a previous exaggeration of the knee-jerks. All reflexes are abolished. The affected muscles after a time cannot be stimulated to contraction by the faradic current, though they still retain their reaction to galvanism. Together with the paralysis, and sometimes without it, a certain amount of ataxy is not infrequently seen, most obvious in the legs, though also sometimes found in the arms.

Sensation, in one or all of its varieties, is usually lost to a greater or less extent, but not always in proportion to the loss of muscular power. The distribution of the anæsthesia varies. It may be spread over the whole limb, or appear only in patches. It is usually most marked in the fingers and toes.

These affections of the limbs are usually bilateral, though not necessarily equal on the two sides.

There is scarcely a part of the body which may not be affected by the paralysis, but other parts than those mentioned are comparatively rarely attacked, and only in severe cases. The intercostal muscles may be paralysed, and less frequently the diaphragm, so that respiration becomes difficult or even impossible. The head falls forward, if the patient is in the upright position, from weakness of the neck muscles. The muscles of the larynx are sometimes attacked. The muscles attached to the epiglottis cease to close the orifice of the larynx, and food may then reach the air-passages. More rarely, the muscles of the vocal cords themselves are

weakened or paralysed, and the voice is altered in quality or entirely lost. The bladder and rectum may be affected in severe cases, but generally they are unaffected. Amongst the muscles most rarely attacked are those of the face and tongue.

In the most severe cases it is possible for nearly all the muscles above-mentioned to be paralysed at the same time, so that the patient lies in bed utterly helpless. This condition, however, is extremely rare. More usually, the paralysis recovers in one part while it progresses in another, and as a rule does not recur in a part it has already left. A patient the subject of diphtheritic paralysis is in most danger of heart-failure, for this complication, while liable to set in during the height of the primary disorder, is specially prone to occur during paralysis. The nutrition of the body may fail from the inability to swallow food; and from food entering the larynx pneumonia may arise. In very rare cases death ensues from paralysis of the respiratory muscles. Yet all these dangers are comparatively rare; and usually the paralysis, however severe, after a time gradually and entirely disappears. According to Dr. Gowers, the average duration of the paralysis is from six to eight weeks in cases that recover, but it remains longest in the limbs, and may there last for as long as four or six months.

**TERMINATIONS.**—(1) *Resolution.*—When the attack ends favourably the fever declines by lysis; the membranes soften, separate, and do not reappear; the patient gradually recovers strength, and resumes his ordinary health. The duration of ordinary cases is about ten to fourteen days, but the attack may be prolonged by recrudescences to a much longer period.

(2) *Death.*—Death occurs in diphtheria (a) by gradual asthenia from mal-nutrition; (b) by rapid asthenia from excessive effect of the poison; (c) by cardiac failure; (d) by asphyxia from spread of the membrane to the larynx, or paralysis of the respiratory muscles; or (e) by any of the complications enumerated above.

**ANATOMICAL CHARACTERS.**—*False membrane.*—The naked-eye appearances of the false membrane have already been sufficiently described. When a section of the mucous membrane covered by the exudation is examined under the microscope, the false membrane is seen to consist of either threads or shapeless masses of fibrin, in which are embedded leucocytes, more or less degenerated, red blood-corpuscles, and shrivelled cell-nuclei. In the deeper layers of the false membrane the outlines of epithelial cells can be seen, showing their bodies swollen into a hyaline or granular mass; the nuclei are not visible; and these cells no longer easily take the ordinary stains. No definite line of demarcation between the false membrane

and the true mucous membrane can be seen: the one joins the other gradually and irregularly. The mucous membrane shows swelling and proliferation of its epithelial cells, and is infiltrated with leucocytes. Its blood-vessels are congested, sometimes thrombosed, and hæmorrhages are seen in the tissue. Numerous micro-organisms, of which a fuller account will be given in the next section, are found, not only in the false membrane, but in the tissue of the mucous membrane, its veins and lymphatics. In the later stages, further degenerative changes are found in the false membrane. It is then much more granular, as seen under the microscope; contains numbers of fatty globules and crystals of fatty acids and cholesterin; and swarms with the micro-organisms of putrescence. The false membrane consists in part of an exudation of fibrin elements, but mainly of the products of coagulative necrosis of the epithelial cells. Hence its close connexion with the mucous membrane.

*Glands.*—The swollen glands are, on section, soft, red, and pulpy, resembling splenic tissue. They show the changes of acute lymphadenitis, and contain micrococci. The lymphatics leading to them are also enlarged and inflamed, and contain micro-organisms. Spots of suppuration are occasionally, but rarely, found in the glands.

*Respiratory organs.*—The larynx, trachea, and bronchi may be covered by false membrane. Its characters here are slightly different from those found in the pharynx. It is thinner, somewhat softer, and more easily separated from its attachments. These characters are due to no peculiarity in the membrane itself, but probably to the thinner layer of epithelium from which in this situation it takes its rise. The membrane may be prolonged into the smallest bronchi which can be followed out. More commonly, however, after proceeding down the trachea a little way, it becomes soft, loose, and at last continuous with a thick purulent or mucopurulent exudation, which covers the mucous membrane of the bronchi, but is not attached to it. The lungs may be congested, or show the changes of broncho-pneumonia or of pulmonary apoplexy. Very frequently, too, emphysema or insufflation of the lungs is seen in patches.

The mediastinal glands may be swollen, and resemble in appearance those of the neck.

*Circulatory organs.*—The cavities of the heart, especially those of the right side, contain *ante-mortem* clots firmly adherent to the endocardium. Endocarditis is not found. The muscular tissue of the heart is nearly always softened, and may sometimes show carditis or fatty degeneration. In a few cases, as the writer has found, colonies of micro-organisms may be seen embedded in the muscular tissue. Frequently, and especially if there

has been difficulty of respiration, small punctiform hæmorrhages may be observed beneath the visceral layers of the pericardium and pleuræ. In the malignant form, the blood after death is found to be of a dark chocolate colour, and very fluid.

Pleurisy and pericarditis are only rarely seen.

*Digestive organs.*—The false membrane may be found extending down the whole of the œsophagus, and may affect the mucous membrane of the stomach, and even that of the intestines. The Peyer's patches and the lymphatic nodules of the intestines are swollen, and may sometimes show ulcerations. The liver is congested. The spleen is enlarged, but not excessively so, and on section is found to be softened and pulpy.

*Urinary organs.*—The kidneys, in all cases, show the change of their epithelial cells called cloudy degeneration. When albuminuria has been present during life, the kidneys present the usual appearances of acute parenchymatous nephritis. The organs are swollen, pale in colour, and soft on section. The cortical portion is unduly enlarged, and of a yellowish-white colour. On microscopic examination, the cells of the convoluted tubes, and also those of the glomerular and capsular epithelium are seen to be swollen, and often proliferated. The changes only differ from those of scarlatinal nephritis in being of a less intense degree, less hæmorrhagic, and in being present often in scattered patches rather than diffused over the whole organ. Sanné asserted that in most cases only one kidney was affected, and thus explained the absence of uræmia and dropsical symptoms. This assertion, however, is not confirmed by the observations of the writer or of others.

*Muscles and joints.*—The external muscles, and sometimes those of the heart, may show the waxy degeneration of Zenker. In rare cases the joints may be found inflamed.

*Nervous system.*—Associated with the paralysis, changes have been found in the spinal cord and the peripheric nerves. Degeneration and atrophy of the anterior cornua of the spinal cord have been observed by Drs. Abercrombie, Percy Kidd, Mott, and others, while extensive degeneration of the peripheric nerves was first clearly and fully demonstrated by Déjerine, an observation since confirmed by many others. The degeneration of the nerves is seldom found in the whole of their extent, and may attack the portions near the spinal cord or those more remote. The change corresponds in its distribution and degree with the region and severity of the paralysis. The affected muscles show granular and fatty degeneration.

*PATHOLOGY.*—The older discussions as to whether diphtheria was from the first a general disease with a local manifestation in the throat—comparable, indeed, to enteric

fever—need now be merely mentioned. It is at the present time beyond doubt that the primary local lesion in diphtheria is due to changes at the site of inoculation, and that from this are absorbed the poisonous matters which give rise to the general symptoms. In the false membrane there are found swarms of micro-organisms, most of which, however, are either entrapped by the fibrinous exudation or are the accompaniment of the putrefactive changes going on in the membrane and in its vicinity. Such adventitious organisms are found only in the superficial layers of the false membrane, except in the malignant form, where they may be met with in the deeper tissues, in the thrombosed vessels, and in the lymphatics and glands. In 1883 Klebs discovered a bacillus in the deeper layer of the membrane, which he believed to be the specific organism of the disease. Its relation to the disease was afterwards fully worked out by Löffler in 1884, who showed that its cultivations, when injected into guinea-pigs, produce changes at the site of the inoculation identical with those found in the throat of man, and afterwards the general symptoms of the human disease. Further progress in this direction has been made by Dr. Klein, who, in the *Report of the Medical Officer to the Local Government Board for 1889*, has shown that the bacilli described by Klebs and Löffler are of two different kinds, which he has separated. Both are found in all parts of the diphtheric membrane, but are free from other organisms in the deeper layers. One of these bacilli, styled by Dr. Klein the pseudo-diphtheric bacillus, is not constant in its presence, and can only be cultivated at a raised temperature. The other, asserted by Dr. Klein to be the true bacillus of the disease, grows on gelatine at the ordinary temperature of a room, and has other technical differences which serve for its separation. It grows readily in milk. These bacilli are only found at the site of the local manifestation of the diphtheria and in the neighbouring glands; never, except in cows, in the blood or deeper tissues; so that if they are the cause of the disease, the general symptoms must be due to poisoning by some chemical product of the growth of the bacillus. This poison, or what is believed to be such a poison, has been separated from growths of the bacillus by Roux and Yersin, Fränkel and Brieger, and others; and by means of its inoculation they were able to produce the general symptoms of the disease. The theory, then, which at present best explains the pathology of the disease, is that we have an infection of the throat or of a superficial wound by the diphtheria bacillus, which there takes root, and by the products of its growth infects the whole organism. How its poison produces the general symptoms of the disease we have

at present no theories to explain. Recently, experiments have been made by Behring and Kitasato, Brieger and Fränkel, and Löffler, as to the possibility of weakening the action of the bacillus by various methods, and so conferring immunity against its further action; but, so far, no results have been obtained which are of use in human therapeutics.

The pathology of the cardiac failure so often met with is also obscure. It may be due to actual poisoning of the heart-muscle by the virus of the disease; and this may be the process at work when this accident occurs in the early stages of the fever. The stoppage of heart, though in regard to its symptoms a sudden phenomenon, may be really due to a gradually accumulating weakness. Dr. Sidny Phillips has shown that from cardiac weakness there may be a gradual filling up of the right ventricle by thrombus, accompanied by symptoms scarcely appreciable in the midst of the general febrile disturbance. Sudden death, however, will occur when in the right ventricle and pulmonary artery there is not left sufficient room for the circulation to be carried on. In the later stages, the cardiac failure is probably due to changes in the pneumogastric nerve or its central connexions—changes, however, which as yet have not been demonstrated.

The changes in the nerves have been found to be parenchymatous in nature, except in one case reported by Meyer, where nodular enlargements were seen, due to infiltration of the nerve-sheath. Though the changes are generally described as due to 'parenchymatous neuritis,' there is no proof of their being inflammatory, and the appearances observed are degenerative. In some cases of post-diphtheritic paralysis there is great difficulty in tracing the affection to an antecedent sore-throat, and the question has arisen whether the sequelæ may occur without any specific local lesion. That there may be a non-membranous primary diphtheria has been argued above, and this may be followed by paralysis. A remarkable series of cases illustrating the difficulties in which the physician may be involved, is recorded by Boissarie in the *Gazette Hebdomadaire*, 1881, p. 310, amongst which, during an epidemic, the first symptoms observed were those of paralysis in many cases, in some followed by angina, whereas, in succeeding cases, the disease had its accustomed course.

The albuminuria may be due to several causes. In many cases, of course, the organic changes in the kidney sufficiently account for the symptom. But in other cases, and especially in those where it is an early symptom of the disease and quickly disappears, it would appear to the writer to be due to a disorder of the circulation dependent upon the weakness of the heart's action. This may be combined with organic change, as it is in all cases of Bright's disease, but the essential factor in

the production of the albuminuria is the disorder of circulation.

*Mode of access of the poison to the system.*—Diphtheria is eminently a contagious disorder. A large number of the cases can be traced to actual contact with diphtheritic membrane or the secretions therefrom. Thus, surgeons who, after performing tracheotomy, have sucked out the secretion which blocked the tube, have very frequently contracted the disease, as have also relations who have kissed a patient. The cases alluded to earlier in this article, in which wounds have been inoculated by diphtheritic poison, are also demonstrative of this fact.

But diphtheria is also infectious, as is shown by its spread from one district and from one country to another. It occurs most frequently in epidemics, and yet in the present day it is so endemic in our large towns that they are never free from it. It forms a large item in the regular annual bills of mortality.

Its spread seems to have no connexion with the water-supply. But instances are now numerous in which outbreaks of diphtheria have been associated with a particular supply of milk. Here we may not only have to deal with a mere transference of the poison from man to man, milk being merely the vehicle, as is the case with scarlet fever, but the question also arises whether there may be a disease in cows which is identical in pathology with human diphtheria and capable of producing the latter. Dr. Klein's recent observations are of great importance in this connexion. During epidemics, it had been noted in a few instances that the cows, from which the infected milk had been derived, had had chaps or sores on the teats. Dr. Klein inoculated healthy cows with cultivations of his diphtheria bacillus, and in consequence of this observed not only a local affection at the point of inoculation, and general symptoms too, but also an eruption on the teats and udders. He also succeeded in obtaining cultivations of his diphtheria bacillus from the milk of such a cow, and, further, an outbreak of diphtheria amongst the cats of the Brown Institution was traceable to two cats who had been accidentally fed on the milk of the infected cows. These observations are extremely suggestive, and, if confirmed, will throw great light upon the ætiology of diphtheria.

Medical men have, at different times, attributed outbreaks of diphtheria in man to infection or spread of infection from cats and other domestic animals, but no distinct proof of such a method of attack has hitherto been published. Nevertheless, Dr. Klein has shown that cats spontaneously suffer from a disease which is associated with the presence of his diphtheria bacillus, and also that the same disease is produced in them by inoculation on the cornea with poison derived from human diphtheria. Dr. Klein is ot

opinion that in cats the primary seat of infection, in idiopathic cases, is the lungs.

**ÆTIOLOGY.**—The exciting cause of diphtheria is doubtless an organised poison, and it may be accepted, provisionally at least, that it is the diphtheria bacillus described by Dr. Klein. The means, however, by which this germ obtains access to the body, and is allowed to work its ill effects therein, are of all importance, and constitute the predisposing causes of the disease. These may shortly be discussed as follows:—

1. *Age.*—The statistics of the incidence of diphtheria at various ages have been collated by Dr. Thorne Thorne in his 'Milroy Lectures' for 1891. The greatest number of cases, he remarks, occur between the ages of two and five years, or, more widely stated, between three and twelve years, and this excess may possibly be due to the greater exposure to infection during this period from the aggregation of children in schools.

2. *Sex.*—The disease is more frequent in females, possibly, according to Dr. Thorne, because of the greater danger of infection they undergo in nursing the sick.

3. *Heredity.*—There undoubtedly are some families in whom a more than usual number of cases of diphtheria occur, and this probably is due to an inherited weakness, rendering the members unduly receptive of the poison.

4. *Season.*—Dr. Tatham, when medical officer of health for Salford, published in his reports most careful statistics as to the number of cases occurring in that locality, where diphtheria is especially rife, at various times of the year. Dr. Tatham has kindly furnished the writer with the table which follows, in which it is clearly shown that an increase in the number of cases of diphtheria begins in the third quarter of the year; the number attains its maximum in the fourth quarter, and, while declining in the first quarter, nevertheless is still in excess of the number occurring in the second quarter.

BOROUGH OF SALFORD.

*Reported Attacks of Diphtheria in the several Quarters of the Seven Years 1883-1889. (Dr. Tatham.)*

	First quarters (Jan., Feb., March)	Second quarters (April, May, June)	Third quarters (July, Aug., Sept.)	Fourth quarters (Oct., Nov., Dec.)
Reported cases . . . .	270	233	290	431
Proportion to whole . .	22%	19%	24%	35%
Deaths amongst the above reported cases.	79	62	58	125
Case fatality . . . . .	29%	27%	20%	29%

The table also shows (see percentage of deaths) that in the third quarter of the year

the milder cases occur, and the greatest number of deaths in the fourth and first quarters, the excess in the first quarter being probably due to a legacy of severe cases left from the preceding quarter.

5. *Rank.*—The disease is more prevalent among the poor, probably because overcrowding increases facilities for contagion and infection.

6. *Hygienic conditions.*—There is no doubt that exposure to sewage emanations is a fruitful source of diphtheria. How this comes about is not precisely certain: we do not yet know that the diphtheria-germ grows in sewage, or is given off in sewage-gas. The cases reported by Dr. Hill of perineal diphtheria, already mentioned, tend to show that this might be the mode of infection. Dr. Thorne, however, is of opinion that sewage-gas produces a morbid condition of the fauces which renders the patient more liable to the reception of the diphtheria poison. He makes the very apposite remark that diphtheria has greatly increased of late years, and especially in towns, whilst improvement in hygienic surroundings, and especially in the disposal of sewage, has received much more attention, and in consequence of this, diseases undoubtedly due to sewage infection, such as enteric fever, have greatly diminished. This is a fact which militates against the view that diphtheria is connected with poisoning by sewage, but the statistics of the association between the two are very positive.

In former years, diphtheria was more common in country districts than in towns, or, to speak more accurately, in the sparsely populated than in the densely populated parts. In recent times, as shown by Dr. Longstaff in the *Report of the Medical Officer to the Local Government Board for 1888*, this relation has been reversed, and now diphtheria is the more common in thickly populated districts. The statistics also show that the geological conditions have but little effect on the incidence of the disease. Dr. Thorne, however, asserts that this is only true as regards the structure of the soil itself, in relation to drainage. A clay soil may be rendered immune from diphtheria by the possibility of free drainage. But where moisture is accumulated, and also allowed to remain stagnant, there diphtheria is rife.

7. *Influence of other diseases.*—The way for the diphtheria poison may be prepared by other diseases, such as tonsillitis, rendering the fauces a vulnerable point, or by diseases which weaken the system and so diminish its power of resistance. Probably the puerperal state should be associated with the latter group of conditions.

In most works on diphtheria hitherto published, it has been customary to speak of a primary and of a secondary form of the disease. The former is that ordinarily met with. By the latter is understood the occurrence

of diphtheritic lesions and symptoms after various other diseases, amongst which the principal are scarlet fever and measles. It must be remembered in connexion with this subject, that the mere appearance of a false membrane is not a proof of the existence of diphtheria. The same process, coagulative necrosis, which is the main factor in producing the diphtheritic membrane, also takes place on mucous surfaces as the result of many other intense inflammations. Thus, in scarlet fever, the occurrence of a false membrane on the fauces may be due only to a specially irritative effect of the scarlatinal poison. Nevertheless, cases not infrequently occur—and the writer has had many opportunities of examining such—where, together with positive symptoms of scarlatina, large quantities of diphtheritic membrane have formed in the throat, and have even extended to the larynx, and where also after a time the characteristic paralyses of diphtheria have shown themselves. Such cases are specially prone to occur when epidemics of scarlet fever and diphtheria co-etaneously exist, and there is reasonable ground for believing that they are due to a dual infection by the poison of both diseases. In attacks of 'scarlatinal diphtheria' a special streptococcus has been found by several observers, but the evidence of its identity is still incomplete.

8. *Previous attacks.*—One attack of diphtheria confers no immunity upon its subject. Even during convalescence the patient has been known to incubate the disease afresh, and this process may be repeated more than once.

DIAGNOSIS.—Almost any affection of the throat may be mistaken for diphtheria, but the mistake is only likely to happen in the case of acute follicular tonsillitis, scarlet fever, and syphilitic affections. Their points of difference may be summarised thus:—

1. *Acute follicular tonsillitis.*—Here the amount of fever may be equal to or even greater than that found in diphtheria. Usually the fever begins more suddenly, without prodromata, and is accompanied by more pain in the throat and more disagreeable general symptoms than occur in the early stage of diphtheria. In fact, the less serious disease has in most cases the more severe symptoms. In acute follicular tonsillitis, even from the first, exudation can be seen issuing from the tonsillar crypts, forming many small white points upon the surface of the swollen tonsils, and nowhere else. In diphtheria some hours, or even days, usually elapse before more than one patch of membrane is seen, and this may possibly not be upon the tonsil; or, if there be more than one, a patch situated elsewhere than on the tonsil will decide the diagnosis. The diphtheritic membrane, too, soon becomes thick and leathery, and is not

easily removed, while the exudation of tonsillitis remains soft and creamy and is easily wiped away with a brush. In acute tonsillitis nasal catarrh is not often met with, while in diphtheria of moderate severity it is frequently an early symptom.

2. *Scarlet fever.*—Diphtheria rarely begins with the same suddenness as scarlet fever; and vomiting, too, is not usually an early symptom. The temperature in scarlet fever rapidly rises to a height which is rarely found in diphtheria, and then only in the later stages of an acute attack. After twenty-four hours, too, the scarlet-fever rash appears. This may possibly be mistaken for the erythema rarely seen in diphtheria. But the diphtheria-rash, when present, does not spread over the whole body, being limited to the upper parts of the chest and the neck; it is not punctate; and it is never an early symptom. The special albuminuria of scarlet fever first makes its appearance late in the disease or at the beginning of convalescence; and if albuminuria should occur earlier, it is only slight, and such as may accompany any febrile state. The urine, too, in scarlet fever frequently contains blood together with the albumen. In diphtheria, on the other hand, albuminuria is an early symptom; and in a doubtful case, if the urine contains much albumen after only two or three days of the fever, a diagnosis of diphtheria is the more probable. The urine in diphtheria rarely contains blood. The throat affections of the two diseases may resemble each other very closely, for in scarlet fever, not only may the slough of the mucous membrane simulate the false membrane of malignant diphtheria, but, as already stated, there may occur in scarlet fever a false membrane having the same pathology as that of diphtheria. Yet, in scarlet fever, ulceration is more prominent than in diphtheria; shreds of membrane are not expectorated, and there is no tendency of the throat-affection to spread to the larynx. The writer has already mentioned, as his opinion, that in the cases where laryngeal affection has ensued upon scarlatinal symptoms, there has been a double infection by the two poisons.

3. *Syphilitic affections.*—Syphilis, in the secondary stage, may produce white patches over various parts of the throat, due to coagulative necrosis of the epithelial cells. These may be mistaken for diphtheritic membrane. But they are never accompanied by so much fever as occurs in diphtheria; they are not so raised as diphtheritic patches; and the parts around are not so swollen as in diphtheria. Moreover, the rash of secondary syphilis present on the body-surface at the same time is diagnostic. The ulceration of the throat which may appear in the tertiary stage of syphilis might be mistaken for a diphtheritic condition during an epidemic of diphtheria; but the remembrance of the possibility of its

occurrence should be sufficient to remove the chance of error.

The paralysis of diphtheria has the characters of paralysis due to peripheral neuritis, in the article upon which subject details will be found as to its diagnosis. The special characters distinguishing it as of diphtheritic origin are—the history of the throat trouble, if this be obtainable; the peculiar progress of the paralysis; and the early affection of the palate and eyes, which are rarely touched by other forms of peripheral neuritis. See NEURITIS, PERIPHERAL.

PROGNOSIS.—The prognosis in diphtheria must always be guarded, even in the mild cases, for serious symptoms may at any time break out. The prognosis is the more serious the greater the quantity of membrane to be seen in the throat, the higher the temperature, and the greater the weakness and the severity of the general symptoms. The early signs of heart-failure—namely, an unduly slow or very rapid pulse, and the alterations in the cardiac sounds already detailed—are warnings of impending great peril. The malignant form is nearly always fatal; and consequently the occurrence of much hæmorrhage from the throat or nose, a gangrenous condition of the false membrane and surrounding parts of the throat, or signs of much nasal affection, are of grave significance. The occurrence of albuminuria adds nothing at all to the severity of the original disease, and therefore is *per se* of no consequence in judging the prognosis. But, with this exception, any one of the complications mentioned above adds to the gravity of the attack. This is especially the case with extension of the disease to the larynx, which, if unrelieved by operation, in nearly all cases will kill the patient. After operation, too, a large number of patients die either from the severity of the original attack, or from extension of the membrane down the bronchi and consequent occurrence of diffused pneumonia. In the experience of the writer, those cases of laryngeal diphtheria which have followed on scarlatinal symptoms are specially fatal. Generally speaking, the prognosis is the less favourable the younger the subject.

The prognosis of diphtheritic paralysis is on the whole favourable. Nearly always the paralysis recovers. The unfavourable cases are those in which the muscles of the larynx and those of the trunk are paralysed.

TREATMENT. — 1. *Prophylaxis*. — Diphtheria is undoubtedly both contagious and infectious. The infection lies in the exhalations of the patient, and especially in the portions of false membrane expelled from the throat. For this reason it is necessary that a case of diphtheria should be stringently isolated, and that all false membrane coughed up should be at once received into a vessel containing an antiseptic fluid, such as carbolic acid (1 in 20) or perchloride of mercury (1 in

500). During the course of an epidemic no milk should be partaken of by healthy persons unless boiled shortly before being used. In the light of our present knowledge, doubtful though this may be, it would also be well to banish cats and birds from a household during an outbreak of diphtheria. Löffler has fixed eight days after the apparent disappearance of the disorder, as the period during which a patient should remain in quarantine.

2. *Surroundings of the patient*. — The patient should be kept in a warm, well-ventilated room. If there is any sign of affection of the respiratory passages the air of the room should be kept moist, and this may be effected by allowing the nozzle of a bronchitis-kettle to enter within the covering of a tent-bed. A warning may here be given that, without due care, *cool* and not *hot* moisture may thus be supplied to the patient, and may be extremely harmful by depressing the vital powers and inducing pneumonia. Heed to this point is especially necessary after the performance of tracheotomy.

3. *Diet*. — The extremely weakening effect of diphtheria must always be borne in mind, and every effort made to help the patient to assimilate nutriment during the attack. This, however, is a difficult matter, for not only does the patient frequently loathe food, but if, in spite of this, it be administered in injudicious quantities, vomiting may be set up, which will totally preclude nutriment being given in the ordinary way. In these matters the judgment of the careful physician may be taxed to the utmost, and must decide on the merits of each individual case apart from any general laws. As a rule, milk must be the staple article of diet. It may with advantage be peptonised, and mixed with lime-water or soda-water in the proportion of 2 in 3. It should be given at intervals of two hours, or, if only small quantities can be taken at a time, every hour. With it, twice or thrice a day, the yolk of an egg may be beaten up, or arrowroot boiled in milk may occasionally be substituted. Again, strong beef-tea should at intervals be given, not only as a relief to the milk-diet, but also for its stimulant effects. If the condition of the throat do not debar the patient from swallowing them, beef-jelly, or chicken- or beef-essence, may be given similarly. Where milk disagrees, raw beef-juice will sometimes be found of great value. Children will not infrequently refuse to swallow food, even when the throat-affection does not interfere with its passage. Here two means may be made use of to maintain the nutrition: either the child may be fed by the nasal tube, a disagreeable proceeding which is rarely applicable in diphtheria, or the feeding may be carried on *per rectum* by means of nutrient enemata or suppositories. The latter method must always be resorted to when severe vomiting prevents food being given by the mouth.

4. *Stimulants.*—Alcohol is needed in every case of severe diphtheria, and is best given in the form of champagne or brandy, at intervals of two or three hours, in quantities proportionate to the age of the patient and the severity of the attack. It must always be given freely when any of the signs of cardiac failure are perceived.

5. *Internal medication.*—Of recent years rational therapeutics has been employed with great advantage in the treatment of diphtheria. The disease has long been thought to be due to the action of germs or of the products of their growth, and for this reason many germicide remedies have been proposed. Quinine was used before any such theories were mooted, but is a most valuable remedy. Again, the perchloride and also the periodide of mercury have been employed with great success. The perchloride of mercury,  $\frac{1}{2}$  to  $\frac{1}{4}$  of a grain, with sulphate of quinine 2 grains, administered to an adult patient every third or fourth hour, is an efficacious combination. The periodide of mercury can best be given in the soluble form recently introduced by pharmacists. A still more powerful drug, the cyanide of mercury, has been recommended, but cannot be other than a dangerous remedy. Salicylic acid and its compounds, too, have been used with apparent benefit. Of the older and empiric remedies, perchloride of iron and chlorate of potassium have been the most employed, and are undoubtedly of great value. They may be given in combination together with glycerine, and the iron should be administered freely so long as vomiting does not occur. The general antifebrile remedies may also be given in diphtheria, but acids are preferable to alkaline compounds, since the latter are depressing to the circulation. On no account whatever should antifebrin, antipyrin, or any of the so-called new antipyretics be used in diphtheria.

The number of other drugs which have been employed in the treatment of this disease is very large, but as the writer has no experience of them he can do no more than mention them. Amongst them are peroxide of hydrogen, hyposulphite of sodium, and turpentine, not to say chloral and jaborandi, which in the opinion of the writer are dangerous.

The older physicians frequently administered emetics in diphtheria, with the object of detaching and expelling false membranes from the air-passages and throat. Their results from this treatment were often good. But now that more is known of the heart-failure so common in diphtheria, and of the depressant effects which emetics have upon the circulation, they are used more rarely. If employed at all, only the least depressant, such as sulphate of zinc, ipecacuanha, or apomorphine should be given.

6. *Local remedies.*—The throat is the

locality from which the specific poison of diphtheria is absorbed into the system, but it is very doubtful whether remedies applied thereto are of any effect upon the poison itself. Nevertheless, we have in diphtheria a poisoning by general septic matter, the result of the putrefactive changes going on in the throat, and much good can be done by remedies which arrest this process. No force whatever should be used to remove the membranes, but the throat should be sponged out frequently with a solution of perchloride or mercury (1 in 500), of carbolic acid (1 in 40), or of resorcin (1 in 20). An excellent application, too, is the solution of the perchloride of iron, either alone or mixed with an equal quantity of glycerine. The tincture of iodine applied locally has also been found very beneficial.<sup>1</sup> These applications may be alternated with the use of the carbolic spray. A large number of other applications have been recommended at various times, but those just mentioned will be found the most useful. Many of those which have been used have no other merit than that of being harmless. Some, such as papain, &c., have been recommended because they had the power of dissolving diphtheritic membrane outside the body. They have, however, not been found so efficacious in dissolving the membrane *in situ*; and, if they had been, they would only have been of use when the membrane attacked the air-passages. Their thorough application, in such conditions, is difficult or impossible, and, moreover, in the same circumstances, other treatment is more urgently required.

7. *Treatment of certain complications.*—

(a) *Spread of the membrane to the air-passages.*—In view of the extreme fatality of this complication, operative treatment is at once called for, as soon as it is diagnosed by the signs already detailed, even though it be in an early stage. The opinion of surgeons is as yet divided as to the comparative merits of tracheotomy and Dr. O'Dwyer's intubation of the larynx, but one or other operation must be performed. It is true that even after this the prognosis is still bad, for death from pneumonia is very common; yet the best chance has been afforded to the patient.

(b) *Spread of membrane to the nares.*—When this occurs, antiseptic solutions similar to those used for the throat should be injected frequently into the nares. Care, too, should be taken to quickly wipe away all secretion issuing from the nostrils, in order that excoriations and secondary infection may be avoided.

(c) *Vomiting.*—This is best treated by the sucking of ice, and the administration of carbolic acid, creasote, or bismuth. Ice to the

<sup>1</sup> In a note to the writer, Dr. Adamson, of Rye, reports highly of the *internal* use of tincture of iodine in frequent doses of 3 to 7 minims. It produced no ill effects, and was easily taken.

epigastrium, or a blister over the epigastrium, will frequently be of use; but if a blister be used, care must be employed that the resulting sore be not infected by the diphtheritic membrane. If the vomiting is severe, food must be given by the rectum.

(d) *Heart-failure*.—Here free stimulation must be resorted to, both during the attack and when it is threatened. During the attack remedies are not of much avail, for death is so frequently sudden; but, if possible, nitrite of amyl or nitroglycerine may be administered. The subcutaneous injection of liquor strychninæ hydrochloratis in doses of three minims repeated every half hour (for adults) will sometimes tide the patient through the dangerous period. When the signs of heart-failure are perceived, even if the patient is apparently convalescent, he must be kept in the recumbent posture at absolute rest. General tonic remedies should be given, together with strychnine, iron, and digitalis.

(e) *Paralysis*.—For this complication the most efficacious remedies are good diet, good air, and the administration of iron and strychnine. Massage, when the extremities are affected, is often of value, and the application of a weak faradic current seems sometimes to promote recovery.

ROBERT MAGUIRE.

**DIPHThERITIC**.—Relating to diphtheria. The term is applied to the membrane formed in diphtheria; and it is also associated with certain symptoms occurring in the course of the disease, such as diphtheritic paralysis. See *CROUPOUS*; and *DIPHThERIA*.

**DIPLOE**, Diseases of.—See *SKULL*, Diseases of.

**DIPLOPIA** (*διπλός*, double; and *ὄπτομαι*, I see).—Double vision. See *STRABISMUS*.

**DIPSOMANIA** (*δίψα*, thirst; and *μανία*, madness).—SYNON.: *Oinomania*; Fr. *Manie Ébrieuse*, or *Crapuleuse*; Ger. *Trunksucht*.

**DEFINITION**.—An irritable condition of the nervous system, characterised by a craving, generally periodic, for alcoholic and other stimulants.

**ÆTIOLOGY**.—This peculiar condition may be brought on by a course of intemperate drinking; but it is seldom the result of that cause alone, and is not infrequent in persons who have never been intemperate prior to the development of the morbid craving. The occurrence of this form of insanity, as of other degenerative nervous diseases, may generally be traced in the family history of the patients. But sunstroke, a blow on the head, or other direct injury to the brain may excite it; and it may be symptomatic of epilepsy, or of structural disease of the brain. It may be developed at any period of adult life; but most frequently declares itself during the pubescent and climacteric periods.

**SYMPTOMS**.—An instability of character and indications of peculiar nervous irritability may generally be recognised as having preceded the distinct development of the craving. It is also usual to find such persons as are predisposed to the disorder abnormally sensitive to the influence of stimulants. Sometimes very small quantities of alcohol produce appreciable intoxication. The duration of the periods of craving is variable; but most commonly they last one or two weeks. The remissions continue for periods varying from two to twelve months. During the period of craving the whole moral being is enthralled by the morbid desire; and the regard for truth, decency, or duty is generally altogether lost. Moderate indulgence in a stimulant may bring on the morbid craving; but the desire is frequently developed without any such introduction. Members of the household in which a patient lives can indeed often recognise the indications of a coming attack by a restlessness and depression which precede any such indulgence. During the intervals the patient seems, except when the brain has been weakened by frequent attacks, to recover completely; and he generally displays great confidence in his ability to resist the tendency in future. Repeated attacks always produce a permanent degradation, both intellectual and moral; and if the patient live long enough he lapses into a state of dementia. It sometimes happens that some cerebral lesion, of which the dipsomania had been symptomatic, manifests itself in paralytic or convulsive symptoms; and the appearance of such phenomena is often accompanied by a modification of the craving.

**DIAGNOSIS**.—True dipsomania may easily be, and often is, confounded with mere habitual drunkenness. In dipsomania, however, there is, as a fundamental condition, a pathological condition of the brain which manifests itself irrespective of external circumstances of temptation. In habitual drunkenness the craving consists mainly in a desire to keep up a condition of stimulation to which the brain has become accustomed. The habit is the result merely of compliance with a vicious custom, and there is no such periodicity or independence of external influences in the symptoms as is found in the true disease.

**TREATMENT**.—Prolonged abstinence from stimulants, and adherence to the tonic regimen, are the only measures from which any amelioration can be hoped for. It is seldom possible to restrain the gratification of the craving without compulsory seclusion; and even when this has been successfully enforced for a considerable period, the morbid tendency is seldom eradicated. By the 'Habitual Drunkards Act, 1879,' amended and made perpetual by the 'Inebriates Act, 1888,' a person who is, by reason of habitual intemperance, at times dangerous to himself

or others, or incapable of managing himself or his affairs, may, upon his own written application, attested by two justices, be admitted into a licensed 'Retreat,' and detained for such period, not exceeding twelve months, as he may specify in such application. Several retreats have been licensed under the provisions of this Act for the treatment of dipsomaniacs, with, in many cases, satisfactory results.

JOHN SIBBALD.

**DISCRETE** (*discerno*, I separate).—This adjective is used in reference to certain cutaneous eruptions, in which the spots or pustules are separate from each other; for example, discrete small-pox as distinguished from confluent.

**DISCUTIENTS** (*discutio*, I drive away).

**DEFINITION.**—Local applications which are supposed to remove or disperse the congestion and effusion of inflamed parts, and the swelling of the skin over them.

**ENUMERATION.**—The chief discutient measures or agents are:—Friction; Pressure; Warm moist applications; Counter-irritation by blisters or liniments; Mercury and its preparations; Iodine and its preparations, including the Iodides of Potassium, Lead, and Cadmium.

**USES.**—These remedies are generally applied over enlarged joints, enlarged glands, or cystic tumours. The most powerful amongst them are blisters, which sometimes remove enlargements with great rapidity; next to these come mercury and iodine and their preparations, either alone or in combination. Their action is aided by heat and pressure. The effect of the former is seen in the Indian treatment of goitre, which consists in rubbing iodide of mercury ointment over the tumour, and exposing the patient to the full rays of the sun, or to the warmth of a large fire. The beneficial effects of pressure are observed in the diminution which takes place in enlarged and swollen joints under the application of mercurial ointment or strapping, the friction with the hand in applying the ointment, and the pressure exerted by the strapping greatly increasing the efficacy of the mercurial preparation in removing swelling. See FRICTION.

T. LAUDER BRUNTON.

**DISEASE** (*dēs*, from; and *aise*, ease).  
SYNON.: Fr. *Maladie*; Ger. *Krankheit*.

**DEFINITION.**—Disease may be defined as a deviation from the standard of health in any of the functions or component materials of the body. See PATHOLOGY.

The expression 'a disease' is frequently used with reference to a supposed unit of causation. Thus, it may be applied to some simple phenomenon, for example, neuralgia, when that phenomenon is the sole effect of a cause, such as a carious tooth; or it may include many concurrent or consecutive result-

ant phenomena, such as those of syphilis or typhoid fever.

**GENERAL CONSIDERATIONS.**—It is well known that changes of function and of structure are brought about and influenced by a great variety of agencies. These agencies, some of which act from within, others from without, are recognised as the *causes* of disease. Such changes, whether they be functional, affecting more especially the vital properties of the body without manifest alterations of structure, or structural, clearly affecting its physical properties, constitute what is familiarly known as DISEASE, which is hence said to be *functional* or *structural* respectively. These changes are merely the evidence of an altered or perverted action, which is then in operation or has already occurred, the nature of which is considered under the head of PATHOLOGY. When these deviations from health can be recognised during life they are described as the *symptoms* or *signs* of disease. For example, when a person, after exposure, it may be to wet or to cold, or both, is found to have an increase of temperature, with a quick pulse and perverted secretions, to complain of thirst, and of pain at the joints with effusion in and around them, we say that such person is labouring under disease; and we call it 'rheumatism,' because that name has been assigned to a complexus of deviations from health, such as those then presented by this individual. When typhoid poison has been introduced into the body, it leads in like manner to a number of functional and structural changes, which, taken together, constitute what we call 'typhoid fever.' Or, again, under certain circumstances there appears to be generated in the system, whether as the result of a tendency established before birth (hereditary) or by habits of life (acquired), an agency which, acting morbidly, produces a series of phenomena which we call 'gout.' These several forms of disease may be *classified* in groups, arranged in accordance with the causes which give rise to them, or their nature, their seat, their duration, &c. Rules are laid down for the modes of distinguishing or *diagnosticating* one disease from another; for *prognosticating*, as far as may be, their result; and for their *prevention* and *treatment*.

Thus it comes that the discussion or description of any *particular disease* consists of an account of the causes that give rise to it, or its *Ætiology*; the changes of structure or of function which constitute it, that is, its *ANATOMICAL CHARACTERS* and *PATHOLOGY*; the phenomena attending these changes, otherwise, the *SYMPTOMS* and *SIGNS* of the disease; the facts that serve to distinguish this particular disease from other diseases, that is, its *DIAGNOSIS*; the means of forecasting its progress and termination, which constitute its *PROGNOSIS*; and finally the

measures by which it may be prevented, relieved, or removed, that is, its TREATMENT. Throughout this work the various diseases are, as far as is practicable, discussed upon this uniform plan.

It is well to remember that, as thus understood, DISEASE is an abstract or relative term, and not an entity having a special and independent existence. Physiology has in recent days diffused a clear and penetrating light over many of the processes of life in health, which were previously dark and obscure. Pathology, which is physiology applied to the study of unhealthy function and structure, earnestly follows the footsteps of the sister science. We are therefore not hoping and believing too much when we express our conviction, that the time is not remote when we shall be able to trace those early and subtle changes which constitute disease, as well as the causes which give them origin, and that we shall thus be enabled to define in a more philosophic form and with more practical results what disease really is. In the meantime we must be content to work upon the phenomena before us, to investigate so far as we can the causes of disease, how to recognise its presence and its nature, how to estimate its progress and its duration, and finally how to prevent its occurrence or to cure it when it has occurred. These varied and important points will be found discussed, as above stated, under suitable headings, in the articles immediately following, and in other parts of this work.

RICHARD QUAIN.

**DISEASE, Causes of.**—DEFINITION.—Whatever is capable of damaging the structure of any organ or tissue of the body, or of interfering with its function, may be a cause of disease. This definition implies that such causes are numerous, and that of many of them science is yet ignorant. To give a succinct account of them is therefore difficult, nor is the difficulty diminished by the fact that, in most diseases, we can trace a succession or combination of causes.

**GENERAL CLASSIFICATION.**—The causes of disease have been divided into (1) *Predisposing* or *Remote*, and (2) *Exciting* or *Proximate*. Illustrations will explain what is meant by these terms:—Two individuals are exposed to the contagion of typhus in equal degree; one, wearied by bodily and mental labour, ‘catches’ the disease—that is to say, his condition has *predisposed* him to the exciting cause of the malady; the other, in vigorous health, escapes the contagion—the *exciting* cause of disease. Predisposition in fact *prepares* persons by rendering them more susceptible to the influence of exciting causes of disease. Many persons are *predisposed* to emphysema because of heredity; they contract bronchitis, which, by its attendant cough, easily *excites* the malady.

Such illustrations might be extended to a multitude of diseases. Predisposition may be inherited; or it may be acquired, and be due to various accidental causes. In most cases there is a combination of predisposing causes; in a man, for example, lowered by fatigue, want of food, exposure and debauch, an attack of bronchitis or pneumonia will be readily excited. Though where many factors unite in creating the predisposition to disease, it is not infrequently possible to estimate the part played by each, yet practically it is often difficult to say even how much is due to predisposition.

Moreover it is not always easy to distinguish predisposing from exciting causes. Predisposition carried to excess becomes in some cases an exciting cause of disease, and often there is a combination of both causes. There are certain distinct exciting causes—for example, heat, cold, or injuries of various kinds; but most of these can also claim a predisposing power. The contagia of specific diseases are good examples of direct exciting causes.

In proceeding to discuss the subject of ætiology, no attempt will be made to separate definitely predisposing from exciting causes of disease. The writers will endeavour rather to indicate as far as possible, under the head of each factor of causation, the direction in which it especially acts.

The following causes will be considered: (1) *Race*, (2) *Heredity*, (3) *Sex*, (4) *Age*, (5) *Intermarriage*, (6) *Temperament*, (7) *Climate*, (8) *Town and country*, (9) *Hygienic conditions*, (10) *Occupation*, (11) *Air*, (12) *Previous disease*, (13) *Mental and moral conditions*, (14) *External physical conditions*, (15) *Cold and chill*, (16) *Poisons*, (17) *Diet*, (18) *Epidemic diseases, contagion, malaria, parasites, and growths*.

**1. Race.**—The statements formerly adduced to show the influence of this factor of life in the production of disease, have been of late years subjected to a searching criticism, with the result that many are either rejected as inaccurate, or resolved into other factors, such as climate, dress, and diet.

What is left of them may be thus summarised. ‘Lethargy’ and ‘ainhum’ are diseases peculiar to negroes, who also seem especially liable to small-pox and leprosy. In the same race, on the other hand, hæmorrhoids and calculi are unusually rare; and an almost complete immunity from yellow fever is enjoyed by its members. This immunity is said to be proportioned to the purity of the race, but probably may be lost or diminished by residence in a colder zone (Hirsch). Among Europeans, the manifestations of hysteria and insanity are most marked in the Latin races.

**2. Heredity.**—This is one of the most complex predisposing causes, and is therefore proportionately difficult to estimate. In the first

place it is unquestionable that certain specific diseases, such as small-pox and syphilis, may be directly transmitted from parent to child. The second and more complex problem is to determine whether or to what extent immunity from, or susceptibility to, specific contagia, disordered functions, or diseased tissues, can be transmitted from parent to child. The terms 'temperament' and 'idiosyncrasy' are, as Mr. Hutchinson has pointed out, simply expressions of individual heredity.

A virgin community suffers more severely from an epidemic of small-pox than one in which the disease has long been known. Some kind of transmitted immunity is therefore probable. Some specific diseases run in families. Of these the best example is tubercle, with which have been classed leprosy and even typhoid fever and diphtheria. Here it is probably a predisposition to, not a direct transmission of, the disease in question. There is amongst mankind not only an inheritance of such prominent diseases as phthisis, but of peculiarities in the manner they meet and pass through minor ailments. Thus, in families with a 'nervous history,' we meet with predisposition to headaches of nervous type, irregularities of digestion in the form of diarrhoea and vomiting, and a multitude of conditions which have been ascribed to vasomotor disturbances. The members of some families live long in spite of exposure to almost every exciting source of mischief, and contrast most favourably with others who, as far as one can determine, have all things in their favour. There is no doubt that a tendency to gout, the hæmorrhagic diathesis, pseudo-hypertrophic paralysis, Friedreich's disease, hay fever, enuresis, and other diseases is handed down from generation to generation. Of many minor complaints there is less certainty; but it is exceedingly probable that persons are predisposed to bronchitis and other catarrhs by inheritance. It is acknowledged that epilepsy descends from parent to child, and that, in fact, individuals, because of heredity, are often the subjects of nervous diseases excited by causes which those from a different stock are enabled to throw off readily. The various forms of insanity are striking examples. It is supposed that the inheritance lies in the tissues themselves—that there is a something in the tissue-elements which predisposes to certain diseases in certain families. Too much attention is generally bestowed on direct transmission of diseases from parent to child, and too little on tendencies resulting from the sum of forces acting through the innumerable generations of the past. See ATAVISM; and HEREDITY.

3. **Sex.**—There are great differences in the organs and functions of the sexes, and in consequence a great contrast in their predisposition to disease. The female is more delicately constructed than the male, and

those organs which the two sexes possess in common differ in weight and in 'fineness'; and a general consideration at once indicates that the female is less fitted than the male to resist many exciting causes of disease. This is particularly evident at climacteric periods of life: with the onset of puberty girls suffer far more than males, and especially from a variety of reflex spasmodic disorders, which require but little provocation for their development. All the phenomena classed under the head of hysteria often occur at this period. At the same time, and shortly afterwards, there is a tendency to ulcer of the stomach, to persistent constipation, to peculiar attacks of neuralgia—especially of the intercostal nerves, and to acute rheumatism, lapsing into the subacute or chronic kind. Anæmia and chlorosis are also commonly met with at the period of puberty, and if then neglected they are apt to persist, and predispose the individual still more to disease. Goitre, too, is more prevalent among females than among males.

Even so early as the period of puberty the external circumstances of the sexes differ, and on this depends, in a certain measure, the difference in their predisposition. Education, domestic habits and customs, and, above all, occupation, play an important part, and these are largely influential in the production of the diseases just mentioned. But, underlying these outside influences, there is inherent in the sexes a difference in predisposition; for when they are exposed, as often happens, to the same surroundings, they suffer from widely separated diseases. Males are more subject to epilepsy, tetanus, gout, diabetes, locomotor ataxy, pseudo-hypertrophic paralysis, hæmophilia, vesical diseases, and acute lung-affections, than females. The list shows that occupations which involve hard mental and bodily work and constant exposure explain some of the varieties in predisposition. It is probable that females are more frequently ailing than males, but very often their illnesses are associated with the menstrual functions, and are trifling in degree; and, though more males are born than females, towards the later years of life the average of the sexes becomes more equally balanced, or even reversed, because the mortality of males is greater than that of females. It is sufficient to allude to the fact that pregnancy and lying-in predispose females to diseases from which males are entirely exempt; and that there is a considerable difference in the sexes as regards venereal affections, both as to predisposition and the effects of the diseases.

4. **Age.**—This has a most important influence as a predisposing cause of disease. In Wagner's *Manual of General Pathology* the periods of age are thus subdivided:—

- (1) Nursing age (infancy)—from birth to 7th-10th month.
- (2) Childhood—from 1st to 2nd dentition.

- (3) Boyhood—from 2nd dentition to puberty.  
 (4) Adolescence—from puberty to 20th–25th year.  
 (5) Early manhood—from 25th to 45th year.  
 (6) Later manhood—from 45th to 60th year.  
 (7) Old age—from 60th onwards.

This division is excellent, but in no definition is there more need to look out for exceptions than in that of age. The term *age* is strictly comparative; some individuals are old at forty, others young at sixty. Persons fail with regard to particular organs while young in years; and, on the other hand, others acquire an increased power in the same as years advance, of which the brain affords an apt illustration. The minor organs of the body betray the like peculiarities, and in the early decay of teeth, the changes in the hair and the skin, we meet with indications of old age though the individuals are young in years. But, generally, the predispositions of the young and old are striking by their contrast. The young are exempt from fatty degenerations, which are so common amongst those of advanced life, and, in consequence, many diseases amongst them are, *cæteris paribus*, less deadly; and not only does age, by reason of the changes which naturally occur as life goes on, predispose to disease, but all outward conditions become changed. Children—speaking generally—are apt to suffer from acute catarrhal affections of the mucous tracts, glandular diseases, skin-diseases, tuberculosis of acute type, 'scrofula,' inflammation of endo- and pericardium, and a variety of complaints traceable to improper feeding, bad ventilation, overcrowding, and to hereditary tendencies. From acute tuberculosis the aged are almost entirely exempt, and in them the manifestations of hereditary tendencies are observed less frequently than in the young. The very young and the very old are equally subject to bronchial catarrh, and the mortality from this disease at each extreme of life is exceedingly great. But in the young the predisposition to this affection is almost invariably associated with catarrh of the intestinal tract, and diseases which indicate a general constitutional depression; while in the old a predisposition to bronchial catarrh is caused by a degenerative change in the lungs themselves, or in the air-passages. During infancy the nervous system is rapidly developing, and during this stage general convulsions and convulsive disorders, such as laryngismus stridulus, result from slight forms of reflex irritation. As age advances the tendency to spasm decreases, and convulsions become much less marked. The nervous system furnishes other illustrations of 'epochal' diseases. From five to fifteen chorea is common, but differs from convulsions in the greater frequency with which girls are attacked (three to one). Hysteria and the various sensations and vaso-motor disorders

which characterise the climacteric period are also largely 'epochal,' and almost exclusively confined to the female sex.

Some of the specific diseases, especially measles, scarlatina, and pertussis, are more common amongst children than adults, which is partly explained by the fact that the latter class have passed through the ordeal of those diseases, and are thus proof against them. Rickets also is essentially a disease of infancy and early childhood.

The onset of puberty is a constant source of predisposition to disease, for with it comes a complete transformation in the mental and physical characters, so that the individual, if not very carefully watched, deviates from even the most perfect health into a permanent tendency to disease. The system at this period—especially in the case of females—is frequently unable to bear anything which interrupts or interferes with its activity. The generative organs undergo great changes, and with them the whole moral and physical nature is altered. At this period of life there is a predisposition to both bodily and mental diseases; and though constipation, want of sleep, and excessive work at school, especially among girls, are important factors in the causation of disease at this time, perversions of any organ or faculty may be started, and, once started, they are apt to continue; so that there is established, literally, a permanent predisposition to disease, and this predisposition swells very largely the list of affections which are dealt with under the generic term Hysteria. Lung-affections—excepting pure bronchitis—are more common at and shortly after the time of puberty than in previous years; but, excepting in the instance of phthisis, hereditary tendencies are less manifested than during childhood. Even hereditary epilepsy is, if postponed beyond early years, likely to be postponed to the period of adult life.

As has been said, the degenerations of organs and tissues begin to show with much uncertainty, but after the fortieth year of life we almost invariably meet with one or other of them. Their degree and their consequences vary with the surroundings of the individual—with his habits, temperament, occupation, and like influences. Diseases of the large vessels are especially common at this epoch, such as aneurysms of the aorta and of the large arterial trunks in the extremities. Henceforward all the diseases peculiar to advancing age become common. The results of previous disease are now declared by a decided predisposition to exciting causes which have been hitherto withstood. Old age is a relative term. A man is old and predisposed to trifling excitants because his lungs have lost their elasticity, or his brain its regularity of circulation, or his heart its vigour: in each of these cases, as in a host of others, the predisposition is

strictly one of degeneration—most frequently of the vascular system. Again, inherited diseases do not declare themselves in some cases till the later years of life, and of this carcinoma is a striking example. The old are predisposed to lowering diseases—low pneumonia or bronchitis; and to a variety of nervous affections which the vigorous can resist. In short, they succumb to insignificant exciting causes, because of the general or partial decay of the tissues and textures of the body.

5. **Intermarriage.**—Intermarriage certainly predisposes to disease, but it is not easy to determine how far its predisposing powers extend. Hereditary influences are thereby intensified. If the practice were confined to carefully selected cases, some advantage might ensue. Breeders of first-class animals practise intermarriage, and thereby develop speed, quality, and endurance in the offspring. It is beyond question that this practice of breeders of racehorses is eminently successful for the time, but it by no means follows that the permanent results are good. We are bound to look not only to the immediate, but to the ultimate results of intermarriage—in short, to decide whether intermarriages predispose to disease, to the injury of the community. But no rule, free from exception, can be laid down on this subject, for beyond all doubt many intermarriages have led to both physical, moral, and mental advantages. There is no doubt that malformations are handed down, and that where these are marked in families it is injudicious for persons to intermarry. Where also serious diseases, such as phthisis, insanity, or cancer, have been met with on both sides, it is most advisable that intermarriage should not take place.

6. **Temperament.**—Temperament is only of importance as expressing certain inherited predispositions to disease. It is not in itself either a predisposing or an exciting cause. Many forms of temperament were described by the older writers. According to them, persons of *sanguine* temperament are disposed to congestions of organs, and hæmorrhages, on comparatively small provocation. *Phlegmatic* individuals are the subjects of those diseases which are readily excited by want of mental and bodily energy and activity. A third set belong to the *nervous* temperament; such persons are easily excited and easily depressed, and are prone among other diseases to hysteria or hypochondriasis. Nervous persons suffer quickly from delirium and other brain-symptoms, which aggravate and render dangerous an otherwise hopeful malady. In the acute specific diseases this is particularly manifested; *nervous* people are undoubtedly predisposed to them, and when once attacked are unduly liable to dangerous complications. Practically we meet with 'mixed' temperaments, though one may especially prevail.

On the whole, much confusion might be avoided if these terms were altogether discarded, and the connotation of each, stated in definite language expressing what is actually observed in each case, substituted. It would then be evident upon how slight a basis statements regarding temperament are often grounded. See TEMPERAMENT.

7. **Climate.**—This includes many factors, all of which may predispose to disease. Amongst these, the influence of altitude, moisture, temperature, season, and soil will be considered:—(a) *Altitude.* Dwellers in mountainous regions suffer with excessive frequency from cardiac hypertrophy and from hernia, though the causes of these should be more properly sought under 'occupation' than 'climate.' 'Mountain sickness' is wholly dependent on barometric pressure, and is only rarely met with below a level of 10,000 ft. The prevalence of both malaria and phthisis is almost inversely proportional to the height of the district above the sea-level. Cholera is most prevalent in valleys and plains. (b) *Moisture.* Dry air is generally considered less provocative of bronchitis than moist, and this disease may be regarded as one of moist climate. (c) *Temperature.* In the tropics various endemic fevers prevail which are unknown in this country, for they cease to exist when the temperature sinks below a certain level (about 60° F.), probably because the micro-organisms concerned in their spread are unable to thrive below that temperature. Frost very often cuts short epidemics in our own country in like manner. Particular organs are predisposed to disease by climate—the liver in the East Indies, the lungs and the kidneys in regions where the temperature is capricious. Tropical heat is essential to the existence of yellow fever, malaria, and dengue; and is an important factor in the production of such diseases as cholera, tropical stomatitis, dysentery, and hepatitis. Heat may kill suddenly, as in sun-stroke and heatstroke, or excite cerebral mischief just short of death, especially in confined, ill-ventilated places. Long-continued heat lowers the vital powers, and may excite such slight diseases as eczema of a simple character, or such grave affections as inflammation of the membranes of the brain. Choleraic attacks in this country usually are associated with exposure to immoderate heat. (d) *Season.* The influence of season may be resolved into the influences of temperature, rainfall, and prevalent winds. Animal parasitic diseases are more prevalent in the summer. Yellow fever, malaria, and dengue are rife in the summer and autumn, when the rainfall is heavy. Deaths from lung-diseases are most numerous in the winter, and from nervous diseases in the spring. (e) *Soil.* No better proof of the tendency to disease dependent upon the nature of the soil can be given than that yielded by the many careful

observations which have shown that where a proper system of drainage of soil-water is carried out, the tendency to pulmonary diseases is very greatly diminished. Clay soils are cold, damp, and impermeable, and favour diseases aroused by these combined agencies; sandy and gravelly soils readily drain themselves, are warm and dry, and thus far tend to protect those who live on them against disease. Climates are also modified by trees, rocks, rivers, lakes, and other physical conditions. Detritus carried down by streams and deposited along their banks or at their estuaries, has, like ground vegetation and its decay, an undoubted predisposing influence in the spread of malaria. The upturning of large tracts with imperfect cultivation is also frequently followed by outbreaks of malaria. Particular districts also predispose to certain diseases. Cretinism is most common in close valleys; urinary calculus is endemic in many districts of Great Britain and elsewhere. In some circumscribed areas in Scotland, in Norfolk, and other districts, individuals are especially liable to stone.

Fogs in large cities depress most people; and it is not too much to say that many diseases may be traced to a predisposition which 'bad weather' has started. Alcoholism has been provoked in this way. It is clear, therefore, that under the head of climate there are many combining influences, which affect the moral, mental, and bodily nature of individuals, and through one or all may predispose to disease. In this country, and probably elsewhere, those who dwell on mountains are less liable to disease than the dwellers on plains—marshy plains especially. New comers are more prone to the endemic diseases of a district than the natives. The best instances of this are dysentery and malaria. It should be remembered, however, that it is not climate alone which varies the predisposition amongst persons residing in different regions; for their habits, diet, and social conditions differ far more than the climate in which they dwell, and predisposition to disease should never be ascribed solely to climatic conditions unless accidental influences have been investigated and eliminated.<sup>1</sup> See CLIMATE.

**8. Town and Country.**—The influences of town and country, as predisposing to disease, require separate consideration. With them may be considered dwellings, and a variety of minor sources of predisposition. The mortality of country districts is less than that of towns, but towns differ in this

respect amongst themselves. The health of the largest city in Great Britain, for example, compares favourably with any of the large manufacturing towns and with many rural communities. It is easy to understand that differences must depend on the occupation, food, and habits of the people, and on their external surroundings—air, light, drainage, and like conditions. In larger towns occupations are more lowering than in country districts; while the physical and mental strain is greater, and has fewer interruptions. Late hours, intemperance, and prostitution prevail in towns; but it is by no means certain that, in proportion to the population, these ills are less frequent in the more remote districts. In towns overcrowding checks ventilation, makes drainage difficult, so that subsoils become saturated, clouds the atmosphere with smoke and dust, intermingles the sexes (amongst the lower classes), so that succeeding generations are stunted in their development, and in a variety of other ways predisposes to disease. But in some towns these evils have been obviated by sanitary measures, and as a consequence towns often predispose less than country districts to diseases due to defective drainage and overcrowding. Some startling illustrations of this fact have occurred since sanitary science has been acknowledged to be of national importance. In villages, for instance, reputedly 'model,' epidemics of disease associated with defective drainage and evil domestic arrangements have decimated the inhabitants, and the virulence of these epidemics has been greater than that of those met with in large towns. The latter are nowadays for the most part better drained than country districts; thus milk-epidemics of typhoid fever have been imported into large cities from isolated farms where the drainage alone seemed to be at fault. Amongst children rickets, scrofula, tuberculosis, and choleraic diarrhoea are far more prevalent in town than country; and the more crowded the population the greater the mortality from phthisis. The mortality amongst young children is far greater in towns than in country districts. Adulterations are an evil in large communities, affecting people of all ages. From many of these country districts are free. Unadulterated milk is now as easily obtained in towns as in the country. So while dwellers in the country may have bad drainage and bad houses, they have pure air, as a rule, and every opportunity of breathing it out of doors. Even the alcoholised drinks in many country districts are home-made and harmless when compared with the adulterated raw spirits taken by the lower classes of large towns. On the other hand, however, dysentery is a disease of villages rather than of towns.

**9. Hygienic Conditions.**—One of the most common causes of disease coming under this head is want of cleanliness. To this is

<sup>1</sup> Imperfect drainage leads to what are popularly known as 'damp walls' in dwellings, and thus predisposes to pulmonary diseases by interfering with ventilation—in fact, by preventing the admission of pure air into such dwellings. This truth bears out the teachings we have derived from Dr. Buchanan's investigations at Ely and elsewhere.

due a variety of skin-diseases, such as eczema of the scalp in children, and diseases caused by pediculi. It interferes with the functions of the skin generally, and by it even a common cold is modified. Clothing is a part of the subject. Insufficient, improper, or excessive clothing are most important sources of predisposition, amongst the rich as well as amongst the poor; for, though the climate of this country is so variable, corresponding adaptations of dress are for the most part neglected. Clothing is used to prevent the loss of heat, which occurs in three ways—by radiation, conduction, and evaporation; and a proper adaptation should prevent undue loss of heat, allowing for the escape, instead of ensuring the condensation, of the secretions from the skin, and should be sufficiently loose to permit the movement of the limbs and thorax. Non-conducting, loosely woven, flexible materials are clearly the best adapted for this purpose. Neglect of these requirements is largely instrumental in the causation of disease, particularly in young women of our large towns. A very common cause of predisposition to disease is neglect of proper bedding. Deficient ventilation and overcrowding are prolific sources of mischief. Overcrowding and insufficient ventilation are among the greatest evils of our chief cities and towns; and not only is it in their homes and workshops that populations are overcrowded, but in their places of recreation and of religious worship. Briefly it may be said that overcrowding predisposes to moral, mental, and physical deterioration; to all communicable diseases, including all septic and parasitic conditions, and especially to typhus fever and tubercle; to pulmonary affections; and to a variety of nervous diseases. By lowering the *morale* of populations it increases all other predispositions, and, in fact, passes into an active exciting cause of disease.

**10. Occupation.**—Occupation acts in two ways as a factor in the production of disease. (1) It may expose the worker to certain deleterious influences which are themselves exciting causes of disease. Of this class the best illustration is furnished by workers in poisonous substances, such as antimony, arsenic, copper, brass, lead, mercury, mineral acids, phosphorus, and indiarubber. Turners, knife-grinders, and stone-masons suffer from inflammatory diseases of their air-passages and lungs, induced by the inhalation of fine particles resulting from their work. Corns, chronic inflammatory nodules, and various deformities are produced in those whose occupation involves constant pressure on any one part. Shoemakers and chair-makers illustrate this statement, the latter presenting a characteristic corn and subjacent pleural thickening in the first right interspace.

(2) Occupation has a still wider predisposing influence. The general health may be

lowered, and the resisting power diminished, by the conditions of life in which many occupations are carried on. Among these are (a) the *breathing of vitiated air* due to overcrowding or to deficient ventilation; (b) *deficient exercise*; (c) *exhaustion*, physical or mental, from overwork; (d) the *excessive use of particular parts* of the body; (e) *exposure* to cold and wet, or to excessive changes of temperature; (f) *improper or irregular feeding*; (g) or, on the contrary, absence of adequate employment. These influences are often combined and their effects proportionately increased.

Physical overwork is often conjoined with exposure and improper or irregular food-supply, and the combination has a marked effect. It has so predisposed armies to disease that their ranks have been decimated by fever, pneumonia, and bronchitis, far more than by actual fighting. Not a few medical men have been affected by the contagia of the acute specific diseases, because when exposed to them they were worn out by bodily and mental exertion, and by protracted fasting.

Many other illustrations might be given. Soldiers are most liable to thoracic aneurysm and sunstroke; and young women with no fixed employment, or exhausted from overwork and anxiety, to hysteria. A coachman who uses for many hours his pectoral muscles in driving, suffers chiefly in them when he has an attack of muscular rheumatism.

Many of the diseases mainly dependent on occupation may be avoided or alleviated by careful attention to hygienic precautions.

**11. Air.**—The question of air has already been alluded to, in considering climate, occupation, town and country, overcrowding, &c., and it is scarcely necessary to dwell much more on its ætiological effects. Air influences the predisposition to disease according to its degree of rarefaction, moisture or dryness, warmth or coldness, and the impurities, mechanical or chemical, which may adulterate it. In the article CLIMATE many of these atmospheric conditions are fully dwelt upon, and their tendencies explained. Impurities in the air are exceedingly prevalent; and mechanical substances suspended in it can excite irritable conditions of the air-passages which may pass on to inflammation, and even destruction, of the lungs. Pharyngeal and laryngeal affections are a common consequence of these impurities, and occur largely amongst certain classes whose occupation loads the air with fine particles as already described. There is scarcely a mineral used in the arts which cannot, by inhalation, excite or predispose to disease. The air may also be rendered impure by chemical agencies, and the moment the normal proportion of its elements is disturbed it becomes a source of disease. Excess of carbonic acid is especially an element of

mischief—causing headache, dyspepsia, and nervous depression. The presence of ammonia and of sulphuretted hydrogen is attended by like results. The human economy is, however, so framed that its organs can often very rapidly throw off the evil effects of these gases when breathed in overcrowded rooms, so that no permanent mischief is established. Poisoned air plays a part in the production of tubercle, anæmia, and lowered conditions generally; but it is an incomplete comprehension of the causes of these conditions to set down all to this one. The air, also, may be poisoned by other gases, such as carburetted hydrogen.

The atmosphere is modified by currents—sometimes to the relief, sometimes to the damage of mankind. Winds can remove sources of contagion—they can ‘clear the air.’ But according to many authorities they can also bring contagion into localities. Cholera and other diseases have, it is said, followed aërial currents, that is, have been carried by them. The influence of winds upon health varies with the individual concerned. Some persons are invigorated by warm south-westerly breezes. A north-easterly wind will stimulate the energy of one person, but reduce another to a condition of abject misery. The colder winds generally exert their tonic action to most advantage during the middle periods of life. While easterly winds prevail, acute lung-diseases prevail, particularly in the aged. Eczematous conditions often owe their origin to the same cause.

**12. Previous Disease.**—Previous disease often predisposes to the same or to some other affection, and no clinical history is of value unless it includes an account of former illnesses. In difficult and doubtful cases a true statement of these often gives the clue to diagnosis, and even patients themselves are alive to the value set upon an accurate account of their life-ailments. An attack of croupous pneumonia predisposes to recurrence, especially during the three months succeeding the attack; and it may leave behind a predisposition extending far beyond the original disease. Chorea, acute rheumatism, tonsillitis, malarial fevers, and epilepsy tend to recur, as also do the ordinary convulsions of children; but in all these and many other cases it is difficult to estimate the exact part played by derived predisposition, because in all the primary predisposition may be the main agent in the subsequent attacks. In practical medicine it is distinctly recognised that certain diseases predispose to disease, and in their case recurrence is, very properly, jealously guarded against. Pertussis is supposed to predispose to measles, and *vice versa*. There is distinctly a connexion between chorea, rheumatism, and scarlet fever, and these diseases may follow one another in any order. Again, previous disease

may leave behind pathological conditions which remain in abeyance, until excited by causes which the healthy individual could readily withstand. Pertussis often ends, to all appearances, favourably, but afterwards the patients may suffer from severe lung-affections, upon trifling exposure to exciting influences. Caseated or calcified tubercles in the lungs may after a long period of quiescence excite acute phthisis; hepatic mischief followed by collection of gall-stones in the gall-bladder may cause peritonitis and other diseases. Slight complaints are even more marked in their predisposing powers than serious diseases. On the other hand, previous disease sometimes protects individuals and communities; for example, vaccination can save nations from the most terrible of epidemics—small-pox. In the case of scarlet fever, typhus, pertussis, measles, &c., an almost perfect immunity is acquired by those who have already suffered from them. Of course, as with small-pox, no one denies that second attacks of these diseases do occur, but such attacks are wholly exceptional.

**13. Mental and Moral Conditions.**—Bad news may cause sudden death, or, short of this, may interfere with the functions of particular organs. Sudden mental worry may excite dangerous interference with digestion, or start an abnormal cardiac rhythm. Fright has turned the hair white within a few days or hours in healthy persons. Mental and moral shock may check or increase the flow of urine, and, in fact, may affect all the excreting and secreting organs of the economy. Mental overwork may excite cerebral symptoms of a dangerous and even fatal nature, probably dependent upon a general inflammatory hyperæmia. It may also increase the predisposition to tubercular meningitis. Undue or sudden emotional disturbances can excite serious mischief, just as they can predispose to it. Again, the mind is affected by imitative influences; thus a single hysterical patient may arouse in others symptoms almost identical with her own. The subject of the direct influence of the mental and moral state on disease is, however, too wide to be here dwelt upon.

**14. External Physical Conditions.**—These are very numerous as exciting causes of disease. Violent or over-exertion may cause herniæ, hæmorrhages, as from the vessels of the lungs, cerebral congestions, and even ruptures of the valves of the heart, and in one or all of these cases lead directly to death. Over-exertion with the voice may be followed by pharyngitis or laryngitis. Syncope has occurred in the most healthy from violent exertion in hill-climbing, in boat-racing, walking and running matches, &c., acute dilatation of the ventricles probably occurring. In less marked cases an ‘irritable heart’ may result. Various forms of direct injury are frequent causes of disease.

**15. Cold and Chill.**—Cold carried to excess may prove fatal at once. The influences of severe cold are described under its own heading, and it is only with the diseases excited by cold in the everyday acceptation of these terms that we shall deal here. See **COLD**, Effects of Severe or Extreme.

Cold is the most common cause of disease in temperate climates, especially in the changeable climate of this country. It can excite disease directly, and can affect probably all the organs of the body, causing either disturbed function or organic mischief. Cold, when severe, contracts the vessels; interferes with the circulation, and all vital activity; and in this way may cause death. But it is with moderate degrees of cold we have chiefly to deal. A momentary exposure to a cold draught is as frequent an excitant of disease as general exposure for a long time. A cold draught playing on the cheek may cause facial paralysis, sore-throat, or bronchitis; that is to say, cold applied locally may excite disease in the neighbourhood of its application or in distant organs. It is probable, therefore, that cold may act in several ways: (1) it may interfere with circulation; (2) it may affect the extremities of nerves and excite disease by reflex action; or (3) it may check secretions of the skin, the mucous membranes, or other parts.

We cannot wonder, therefore, that diseases of the throat, larynx, and lungs are frequently excited by cold. Bronchitis and pneumonia are its most common results; and as the young and the old are less capable of enduring cold than adults, its results are, in their case, more frequently fatal. Diarrhœa, renal diseases, congestion of the liver, acute and chronic rheumatism, simple dyspepsia, and a host of other affections, are traceable in many instances only to cold. Predisposition has much to do with the effects of cold: some individuals suffer from one form of disease when exposed to it, others from entirely different affections. In some, 'a common cold' is most evidenced by severe muscular pains and fever, in others by a nasal discharge, in others by headache, and so on. Some persons never suffer from 'cold' without having an attack of herpes labialis; and some are most prone to 'catch cold' whenever the weather suddenly becomes warm. Numerous similar idiosyncrasies might be given. The effects of cold should always be considered in almost all predisposing causes of disease. 'Cold' is a vague term and not thoroughly understood; there is, therefore, all the more reason why, when it comes under consideration in individual cases, its precise effects should be most carefully considered and recorded.

**16. Poisons.**—Poisonous gases are powerful excitants of disease, and so are poisons generally, whether animal, vegetable, or inorganic. They may kill quickly, or excite

a disease of long-continued or even permanent nature.

**17. Diet.**—Food and drink may by their abuse excite disease, and gluttony is as certainly an excitant as drunkenness, though this fact is often lost sight of. Excess of food does not refer simply to the quantity taken, but to its quality—its nature, richness, and the times when it is taken. *Excess of food* overloads the stomach, makes calls upon it which it cannot meet, and dyspepsia is the result. Excess of food, if digested, charges the blood with materials not demanded by the economy, and disease of excretory organs or fatty degenerations may thus be excited. *Want of food*, by diminishing the resisting power, also predisposes to disease, such as pneumonia and bronchitis. When the *proper proportions of the elements* of food are neglected, disease results, as *e.g.* scurvy from deficiency of fresh vegetables. Rickets, according to Dr. Cheadle, is due to want of fat, while gout is often provoked by a largely nitrogenous diet, and diabetes by an excessively saccharine one. *Particular foods* will immediately excite violent gastric catarrhs in some individuals, while others can bear them perfectly well. Clotted lumps of casein or starchy foods may irritate the alimentary canal of an infant, as well as, from their indigestibility, afford no nourishment. Many deaths ascribed to 'consumptive bowels' are due to this cause. Putrid food is an active poison. Certain kinds of *fish* are poisonous in themselves, and so may be shell-fish and crustaceans. The *Bothriocephalus latus* enters the body through the flesh of the pike; and, according to Hutchinson, leprosy is derived from salted fish. Diseased rye produces ergotism, and diseased maize pellagra. Flesh from animals suffering from 'trembles,' is believed to give rise to 'milk sickness'; trichinosis and the common forms of tape-worm result from the ingestion of beef or pork affected with the particular parasite in question; and some vegetable foods laden with salts of lime have been supposed to cause urinary calculi. Water and milk are prolific sources of mischief, through the impurities they so often contain. The drinking-waters of large towns are usually derived from rivers, and filtration is not a sufficient purification; or, if obtained from a purer source, they may become contaminated in transit or storage, so that disease may be excited by their use, especially typhoid fever. Scarlet fever, cholera, and malaria have, according to some, been traced to the same source. Many parasites thus find entrance, *e.g.* the ova of the *Tænia solium* (developing in the cystic stage), *Distoma hæmatobium*, *Ankylostoma duodenale*, *Filaria sanguinis hominis*, and Guinea-worm. Hydatids may be derived from the same source, or conveyed directly to the food from the nose or feces of an infected dog. Diarrhœa, dysentery, Oriental boil, and various forms of

metallic poisoning (lead, copper, arsenic, zinc, and mercury) sometimes owe their presence to the minute quantities taken in drinking-water. Goitre and cretinism have been attributed to inorganic impurity in water. Alcohol is a most extensive source of disease: it causes, when taken in excess, cerebral, gastric, intestinal, hepatic, and renal affections, and can lower the system so far as to predispose to other diseases. *See* ALCOHOLISM; ENTOZOA; and POISONOUS FOOD.

18. **Epidemic Diseases, Contagion, Malaria, Parasites, and Growths** are treated of under separate headings. It is now generally established that the diseases known as the acute specific diseases are mostly direct consequences of some contagium. So among the most common exciting causes of disease we must class the contagia of the several fevers, of syphilis, tubercle, and many others. *See* CONTAGION; PERSONAL HEALTH; and PUBLIC HEALTH.

J. PEARSON IRVINE.  
H. MONTAGUE MURRAY.

**DISEASE, Classification of.**—Various classifications of diseases, or systems of nosology, have been adopted by different writers, but it is beyond the province of this work to discuss these arrangements, neither of which fulfils all that is required, or can be regarded as satisfactory. All that can be done here is to point out the characters upon which the chief divisions of diseases are founded.

The first classification deserving of mention is that into (1) **General** and (2) **Local**. **General** diseases include those in which the whole system is involved from the commencement, and it comprehends as subdivisions: (a) The *acute specific fevers*, and certain other diseases due to the introduction of some special morbid agent into the body from without, or in some instances developed within the system—for example, typhus and typhoid fevers, scarlatina, small-pox, malarial fevers, hydrophobia, syphilis, pyæmia, and septicæmia. (b) The so-called *constitutional, cachectic, diathetic, or blood-diseases*, some of which seem to depend upon the production of deleterious elements within the system, which are capable of recognition, such as rheumatism and gout; while others are independent of any such obvious pathological causes, but are supposed to be severally associated with a peculiar dyscrasia or diathesis—for instance, cancer, tuberculosis, scurvy, rickets. **Local** diseases are those which primarily affect particular organs or tissues, each being liable to its own peculiar lesions. Thus we have diseases of the lungs, heart, stomach, liver, kidneys, brain, and the other organs; of the mucous membranes, serous or fibro-serous membranes, skin, periosteum, bone, and other structures. This division into general and local diseases is useful within proper limits, but it must be

remembered that general maladies are often revealed or accompanied by local lesions, and that complaints which are originally local often more or less speedily set up general disturbance. Moreover, it is still a question whether some maladies are to be regarded as general or local in the first instance. *See* SYMMETRY, IN RELATION TO DISEASE.

Another division of diseases, which applies more particularly to those which are of a local nature, is into (1) **Organic or Structural**, and (2) **Functional**. These terms are self-explanatory, the former implying that there is some organic change in the affected part, which we can discover and demonstrate; the latter indicating that there is mere functional disorder, which is independent of any recognisable lesion. That there are structural changes in many affections which are regarded as functional, is, however, highly probable, though our means of observation are not sufficiently powerful to enable us to detect them. In connexion with each organ, a special classification of its individual complaints under one or other of these primary headings is usually adopted, this subdivision depending upon the affections to which the particular organ is liable. As illustrations of functional disorders may be mentioned disturbed action of certain organs, as of the heart, causing palpitation; derangement of the secretory or excretory functions, as in the case of the stomach, liver, or kidneys; and many nervous disorders. Organic diseases are exemplified by inflammation and its consequences; alterations in growth and development; degenerations; malformations; and new-growths. In this work it has not been deemed advisable to describe the diseases of the several organs according to any definite scientific arrangement, but in some cases an alphabetical order has been adopted, while in others individual writers have had free scope to classify the affections of a particular organ according to their own judgment.

Again, diseases may be classified according to their causation and mode of origin. Thus they are divided into: (1) **Hereditary**, or those which are transmitted either directly from parents to children, or indirectly, as the result of a family taint; and (2) **Acquired**, or those which are developed anew in persons free from hereditary taint. When a morbid condition exists at birth, it is said to be **Congenital**. Other divisions, founded on an ætiological basis, are into: (1) **Contagious or Infectious**, and (2) **Non-contagious**; and into (1) **Specific**, or those diseases which are due to a specific cause, and (2) **Non-specific**.

There are other classifications of diseases, which need only be mentioned here. Thus, according to their intensity and duration, they are said to be: (1) **Acute**; (2) **Sub-acute**; or (3) **Chronic**. Another arrange-

ment, founded on their mode of progress, is into : (1) **Continuous** ; (2) **Periodical**, or affections which come on at more or less definite intervals ; (3) **Paroxysmal**, or those which are characterised by sudden or acute paroxysms ; and (4) **Recurrent**, or diseases which tend to recur. Lastly, according to their mode of distribution amongst communities or in districts, complaints are said to be : (1) **Sporadic** ; (2) **Epidemic** ; (3) **Endemic** ; and (4) **Pandemic**. The meanings of these terms are defined under their several headings, but they are sufficiently familiar as indicating the mode of distribution of the diseases to which they respectively belong.

With regard to the classification of diseases which is likely to be permanently adopted in the future for general use, it is probable that this will be founded on a pathological basis, and that, as our knowledge of morbid conditions and processes becomes more extensive, accurate, and definite, it may become possible to establish a system of nosology which will be both scientific and practically useful.

FREDERICK T. ROBERTS.

**DISEASE, Diagnosis of** ( $\delta\acute{\iota}\alpha$ , apart ; and  $\gamma\omega\acute{\sigma}\kappa\omega$ , I know).—SYNON. : Fr. *Diagnose* ; Ger. *Diagnose*.

**DEFINITION.**—Diagnosis is the art of recognising the presence of disease, and of distinguishing different diseases from each other. The term is also applied to the result obtained.

**GENERAL CONSIDERATIONS.**—The *general principles* only of diagnosis will be here discussed. *Special diagnoses* will be treated of in connexion with the several diseases to which they have reference.

In many respects diagnosis is a subject of great interest and importance. First, in a scientific point of view, it is essential that all knowledge should be accurate. Secondly, accuracy of diagnosis, founded upon a sound pathology, enables us to frame a scientific classification of disease in its diverse forms. Thirdly, it is by an accurate determination of the nature of the disease which may be present in any given case that we are able to anticipate its course, and to employ the right kind of remedies in its treatment. It is imperfection of diagnosis which leads in many instances to an under-estimate of the value of therapeutical agents ; for when the nature of a disease is mistaken we are led to employ improper and unsuitable remedies, the failure of which is then erroneously attributed to the inefficiency of the agents, and not to the unfitness of the treatment employed. If our diagnosis had been correct or complete, the remedy employed would more often have had the desired effect.

In order to arrive at a diagnosis we must study the phenomena or characters of each individual case, and then trace its connexion with those groups of symptoms which have

been previously recognised and described as belonging to special or distinct classes of disease. Assuming that the classification has been already made, we proceed to deal with the means which enable us to identify each individual case, and to connect it with previously classified forms of disease.

**MEANS OF DIAGNOSIS.**—To obtain accuracy in diagnosis we must be prepared with a knowledge of the several forms and the varieties which disease assumes ; we must be familiar also with the functions and structure of the several organs of the body in health. It is by observing and comparing the changes wrought by disease in these functions and structures that we are enabled to discover the presence of, and to determine the nature of, the morbid process going on. In forming, then, a diagnosis in any particular case, the physician must, as far as possible, keep in view the real or the ideal condition of the patient in a state of health. He must endeavour to place him in as natural a position as may be, and as little disturbed by the presence of his attendant, or by external circumstances, as possible. The physician must then obtain a history from the patient himself or from others of the incidence of the disease ; and having done this he must proceed to investigate for himself the condition of the patient.

1. *Previous history of the patient.*—The history implies of course a statement of the age and sex of the patient, as of his home and his employment—each of which may have a special relation to disease. It should also include an inquiry into the antecedent generations of the patient, and how far he may have any proclivity to congenital disease or malformation. This inquiry should have reference to both positive and negative facts. It should extend not only to the previous existence of disease in the family, but also to the absence of particular diseases or types of constitution. The patient's history should include a statement as regards the diseases and injuries from which he may previously have suffered ; the remedies used for them ; and the climatic and other influences to which he has been exposed. Nor must the physician neglect to ascertain the history of any children that the patient may have had, as the nature of disease from which the offspring have suffered in many instances throws light upon the health of the parent.

2. *History of present illness.*—The history of the present illness should include the determination of the date of its commencement ; its probable cause ; its earliest phenomena and its progress as influenced by external circumstances, including treatment.

3. *The present condition of the patient.*—Here we have to deal with two classes of phenomena ; namely (*a*) those feelings or facts of self-consciousness which the patient describes to us—*subjective phenomena* ; and

(b) those signs which we ourselves observe—*objective phenomena*.

(a) *Subjective phenomena*.—The patient describes to us his feelings—as of strength or weakness, of numbness, tingling or pain, of wakefulness or wandering; he can tell of affections of vision, of hearing, of smell, or of taste; of breathlessness, cough, palpitation, or of feelings of sinking or faintness; of difficulty of swallowing, thirst, loss of appetite, nausea or sickness, or various sensations and actions connected with the abdomen; of feelings associated with the genito-urinary organs, such as pain or difficulty in passing water; of cramps, spasms, or other alterations of sensation or motility; or of disturbances of sensibility and activity, &c. Each of these signs of deviation from health will have its own value and significance. The physician must at the same time carefully note how far the condition of the patient is in accordance with his statements, and whether there may not be present some reason or cause for concealment or for exaggeration.

(b) *Objective phenomena*.—In studying the objective phenomena connected with disease, the physician makes use of his special senses, assisted by the several instruments with which modern science has provided him.

First, in matters of *eyesight*, he sees the general aspect and expression of the patient, which will include the colour of the skin (such as may result from the fulness or emptiness of the blood-vessels, from the yellowness caused by jaundice, from the blueness of cyanosis, or from pigmentation, &c.); the presence and character of cutaneous eruptions (especially in the exanthemata); the expression proper, such as that of ease or suffering, and of depression or excitement; the conditions of obesity and plethora, or of wasting and bloodlessness. He will also observe the position of the patient—how he lies, or sits, or stands; how he breathes; the appearance of the eyes, the tongue, &c. Further, the sense of sight will be employed in determining conditions of a local or less general nature. Observation must be made of the size, the shape, and movements of parts, and of their expansion or contraction. With the aid of special instruments, such as the ophthalmoscope, the laryngoscope, the cystoscope, the various specula, sounds, &c., the physician will be able to examine parts of the body of the patient beyond the reach of the unassisted eye. The chest-measurer or the stethometer will render more exact the information already obtained by the eye and hand as to the size and mobility of parts. The use of each of the several instruments above mentioned, as a means of diagnosis, will be found described under the heads of their respective names, or in the article on **PHYSICAL EXAMINATION**.

The sense of *hearing* tells of the character

of the breathing, the voice and speech of the patient, including cough, hoarseness or aphonia, 'aphasia,' &c. But the ear is especially applied to the study by auscultation of the sounds produced in connexion with the heart, the lungs, and other organs. The signs thus elicited will be found fully described elsewhere.

The sense of *touch*, or feeling, will communicate a knowledge of the temperature, of moisture or dryness, of size, shape, elevation or depression, of smoothness or roughness, of the pulse or pulsation, vibration, fremitus, of extent of movement, resistance, softness or hardness, and of fluctuation. The accuracy of the results of these observations by touch may be tested by the use of the thermometer, the calipers, and the tape-measure.

The sense of *smell* aids diagnosis in certain cases. The general odour of the patient may be observed in small-pox, in rheumatism, and some wasting diseases (such as phthisis), and in syphilis; and the odour of particular parts and secretions, as the urine in diabetes, the fæces in jaundice, &c., and in cases of the use of certain drugs, or in poisoning. Information is also afforded by the odour of certain discharges, as in ozæna, leucorrhœa, cancer, &c.

The sense of *taste* is seldom employed in clinical investigation, but the physician may make use of the patient's taste, as in tasting the urine in diabetes.

*Further aids in diagnosis*.—Having thus summarily described the employment of the special senses in diagnosis, and given examples of their use, we may briefly mention some other agencies of more general application. The acuteness of the patient's sense of touch may be determined by the æsthesiometer. The capacity of the lungs may be measured by the spirometer; the strength of muscles by the dynamometer; the contractility of muscles by galvanism; and the force and character of the pulse are determined by the sphygmograph. Constant use is found by the microscope, the test-tube, the spectroscope, the endoscope, and polariscope, which aid in determining the character of the various secretions or morbid products that require to be submitted to investigation. The result of treatment may also be mentioned as an aid to diagnosis, as, for example, when an indurated sore yields to the use of mercury. Again, the knowledge that a person has been in a malarious district enables us to decide on the intermittent nature of certain symptoms that may be present. In some cases it may be necessary to render a patient insensible by anæsthetics, with a view to making a complete examination, or in investigating feigned diseases. The administration of small doses of charcoal has been suggested as a means of determining the presence of a passage through the bowels when more or less obstruction exists.

Such, then, are the means used for taking note of those deviations from health which occur in the several functions and structures of the body, and which constitute what are known as the *symptoms and signs of disease*; these are terms which will be found more specially treated of under the heads, DISEASE, Symptoms and Signs of; and PHYSICAL EXAMINATION.

THE DIFFICULTIES OF DIAGNOSIS.—It need scarcely be said here that the practice of diagnosis is not free from great difficulties. We know how hard it is to obtain in ordinary daily life a reliable account or description of any past or present event. There must be still greater difficulty in obtaining an accurate medical history of a patient's case. He has to tell of facts of which practically he may know much, but scientifically very little. He may be forgetful or ignorant on points about which we most need to be informed. He may be inclined to exaggerate or to suppress facts of material import. Nor are the difficulties less in regard to the *objective phenomena* with which we have to deal. The symptoms of a disease are not always so clear and definite as to mark its nature—that is, to be *pathognomonic*. They are more often slight, undefined, obscure, and to be found with difficulty. The symptoms of one disease may very closely resemble those of another, whilst those of the same disease will vary at different stages, and in different individuals. Again, the symptoms of a disease may be complicated by the co-existence of those of another disease; whilst a symptom sufficiently striking in itself may be common to, and present in, several different diseases. We need only mention, for example, feverishness, pain, cough, breathlessness, and blood-spitting.

These are some of the difficulties which he who has to study the operation of disease in life, has to contend with. He must come prepared for the duty with a knowledge, as we have already said, of the body, its structure and its functions in health, and with a knowledge, too, of those combinations of morbid actions which constitute special forms of disease. For, as regards this latter knowledge, all the observations made would remain as isolated phenomena if they could not in each case be grouped as constituting distinct diseases.

We have thus indicated the difficulties of obtaining accurate knowledge as regards both the subjective and objective phenomena. The difficulties are not less when the exercise of the intellectual and reasoning faculties is called upon to analyse, to compare, and to group these phenomena.

The physician may commence his inquiry by tracing up the history of the case and its several incidents, a method which is called the *synthetical*; or he may commence by ascertaining the present condition of the patient, and going as it were backwards in

his inquiry—a method which is known as the *analytical*. As a general rule, both methods are combined in the practice of diagnosis.

Observers can sometimes arrive at a *direct diagnosis*, aided by the presence of some characteristic symptom or sign of disease. When diseases which are essentially different have symptoms more or less common to both, the physician will have to institute a *comparison* between them, until he finds sufficient evidence, in the presence or in the absence of some distinctive symptom or sign, to satisfy him as to the nature of the disease which is present. By being able thus to trace the absence or the presence of a given symptom, he may be able to *exclude* the possibility of the existence of one or other of the diseases under investigation. These modes of investigation will be found fully illustrated in the diagnosis of the several diseases described throughout this work.

In conclusion, it must be remembered that these investigations, which call for the exercise of the highest mental faculties, should be conducted without prejudice and without haste. We should never be ready to accept as clear that which is obscure, as established that which is open to question; above all, we should remember that, though to err is human, it is our duty to endeavour to ascertain in each and every case, before commencing its treatment, what its real nature is, as far as it may be possible for us to do so. It cannot be too often repeated that the application of a right remedy depends on an accurate diagnosis, and that the prevention and the cure of disease are the aims and ultimate objects of our science.

RICHARD QUAIN.

DISEASE, Duration of.—The duration of a disease signifies the period which elapses between its onset and its termination, in whatever way this may take place. In some instances disease can hardly be said to have any duration, a sudden lesion occurring, which instantaneously, or in a very short time, destroys life; under such circumstances, however, some previous disease has usually existed, though perhaps without giving any clinical evidence of its presence, which determines the occurrence of the sudden event. This may be illustrated by some cases of apoplexy, and of rupture of the heart or of an aneurysm. Most affections, as regards their duration, come under one of the three categories already referred to under the CLASSIFICATION OF DISEASE—namely, *acute*, *subacute*, or *chronic*; but it does not serve any useful purpose to fix upon any definite limit of time as specially expressed by these several terms. See ACUTE; and CHRONIC.

*Acute* diseases are of limited duration, and in many of them this is remarkably uniform on the whole, as may be illustrated by the

acute specific fevers and acute idiopathic pneumonia. Even in such affections, however, there are deviations from the ordinary course, instances occurring in which the duration is longer or shorter than that usually observed, and this fact depends on various circumstances, of which the most obvious are the intensity of the disease in any particular case, the previous condition and surrounding circumstances of the patient, the occurrence of complications, and the treatment adopted. Complaints which are *sub-acute* as regards their duration may be exemplified by many cases of whooping cough and chorea, and by some cases of pleurisy, phthisis, pneumonia, gastric or enteric catarrh, and certain skin affections. A large number of diseases are *chronic* in their duration, and many of these when once established become permanent, whilst others are ultimately capable of being cured. As illustrations may be mentioned organic diseases of the heart, most cases of phthisis, cirrhosis of the liver, chronic Bright's disease, dyspepsia, many skin affections, and also morbid growths in various structures.

Some complaints, as regards their duration, can only belong to one or other of the groups just indicated, but a considerable proportion may in different cases be either acute, sub-acute, or chronic. Again, it must be borne in mind that a disease may be acute or even sudden in its origin, but afterwards may subside into a chronic malady. Certain affections are chronic as regards their entire duration, but are characterised by the occurrence at regular or irregular intervals of acute or even sudden attacks, lasting a more or less definite time, which course of events is exemplified by cases of ague, epilepsy, and asthma.

FREDERICK T. ROBERTS.

**DISEASE, Germs of.**—See GERMS OF DISEASE.

**DISEASE, Prognosis of** (*πρό*, before; and *γνώσκω*, I know).—SYNON.: Fr. *Prognostic*; Ger. *Prognose*.

**DEFINITION.**—Prognosis is the art of forecasting the progress and termination of any given case of disease. The term is also applied to the foreknowledge thus obtained.

**GENERAL CONSIDERATIONS.**—It is a matter of interest and often of great importance to be able to indicate with precision how a case of disease or injury will be likely to advance and terminate. This question must be always present to the physician's mind; and it can rarely be absent from that of the patient and of those who are interested in his well-being. It can thus be easily seen how much depends upon the answer of the physician to the questions constantly proposed to him, How long is this illness likely to last? How is it likely to terminate? If in recovery, will the recovery be complete or partial? If in death, when and how?

**FOUNDATIONS OF PROGNOSIS.**—The knowledge which can give trustworthy answers to such questions as the preceding must be founded upon an accurate diagnosis of the nature of the disease from which the individual is suffering; upon the capability of remedies to control it; and, lastly, upon an estimate of the constitutional and vital powers of the patient.

First, as regards the *nature of the disease*. Some diseases which are mild in their nature run a definite course and end favourably: take, for example, a simple catarrh. Others commence with great intensity, and come to a favourable or unfavourable termination very rapidly: for instance, Asiatic cholera, of which many of the subjects die in less than twenty-four hours from the time of their first becoming manifestly ill. A third group, such as typhus, typhoid fever, and certain of the exanthemata, run a longer and more defined course, seldom terminating in death except after the lapse of many days, nor in recovery except after a period of weeks. Another class of maladies, chronic in character, rarely acute, such as tuberculous diseases of the lungs, render the patient more or less an invalid so long as he lives, and generally end fatally. The like observation will apply to the so-called malignant diseases.

Secondly, the *intensity of the particular attack* affords further grounds for prognosticating the result. Thus, in a fever, great prostration, high temperature, and rapid pulse, indicative of the severity of the disease, must lead to the formation of an unfavourable prognosis; just as great debility and wasting, with disturbance of the nutritive functions generally, would indicate a like result in chronic diseases.

Thirdly, with regard to local diseases or complications, whatever the nature of the disease may be, the *organ affected* must form an important element in prognosis. Thus disease of the brain, or of the heart, or of the lungs, or, in a lesser degree, of other viscera, must, even when not specially severe, be looked upon as affording grounds for anxiety, from a prognostic point of view.

Fourthly, as regards the *constitution, age, and sex of the patient*, it may be safely anticipated that in a patient with a good constitution the prognosis will be more favourable than in a person with a feeble or broken-down constitution. Persons whose vital powers are unimpaired will resist disease, and recover under circumstances which would be fatal to other individuals, in whom, on the one hand, plethoric habits may predispose to acute and rapid changes, or who, on the other hand, by degeneration of tissues or by the existence of chronic disease may be rendered liable to succumb, and that rapidly, to morbid influences which healthier textures could resist and overcome.

Disease is badly borne by the very young

and the very old. In very young children disease rapidly runs its course, favourably or unfavourably. The aged have little power of reaction or of resistance; and disease in them, though less pronounced, more frequently ends unfavourably. In middle life, disease may be expected to assume an acute or sthenic form.

As a rule, sex has little influence on the prognosis of disease, except that usually diseases of equal severity are more amenable to treatment in females than in males. Nervous symptoms are, however, more easily developed in women, exaggerating a condition that might not otherwise be unfavourable. Menstruation, pregnancy, parturition, and lactation have all a certain amount of influence, sometimes favourable and sometimes the reverse, on disease in the female.

Fifthly, with respect to *treatment*: a more or less favourable prognosis may be founded upon the fact that the patient can enjoy all the advantages afforded by rest, diet, change of climate, &c., which may not be available under other circumstances for like cases. It is well known that there are some remedies which have a specific effect upon certain diseases, as quinine upon intermittent fever; mercury in some manifestations of syphilis; iodide of potassium in certain stages of the same disease; and colchicum in gout. In such cases a much more favourable prognosis can, of course, be given than in those for which no such specific remedies are known to exist. Experience, however, tells us that favourable results follow in many other cases in which suitable though not actually specific remedies can be applied.

Taking into consideration, then, the above conditions—the nature, the intensity, and the seat of the disease; the constitution, the resisting power, the age, and the sex of the patient; and the possibility of applying suitable and efficient remedies—we are able, in a large number of cases, to arrive at an accurate conclusion as to what the course and result of a disease will be.

**DIFFICULTIES OF PROGNOSIS.**—Still, to arrive at an accurate prognosis is often most difficult. Disease is not always identical in its character, nor definite in its progress or results. The constitutions of individuals vary, and it is often very difficult to measure their powers of resistance. Remedies, too, vary in their action and their operation; and sometimes we are deceived in the best-founded conclusion as to the results that they can accomplish. There are few physicians who cannot recount errors of prognosis made by themselves or by their colleagues. Many persons now live who were doomed to die; and many persons have died whose death was not anticipated. It is the duty of the physician, when asked for his opinion, to state it honestly, but with great discretion, and in general with as much hope as is

fairly admissible. He must be guarded as to the manner in which his opinion is communicated to the patient, for there are many individuals whose temperament is such that the progress of their disease would be greatly influenced for good or for evil by the expression of a favourable or of an unfavourable opinion. At the same time, the physician must avoid deceit; and if there be risk or danger in communicating an unfavourable prognosis to the patient, he must at least communicate it to some judicious individual amongst the patient's friends. Altogether, too much caution cannot be exercised in stating, in any obscure case, what its progress and result will be. There are many cases in which the medical attendant will be justified in replying that he is a physician, and not a prophet. He cannot always foretell results, his aim and object ever being to mitigate the patient's suffering, to prolong life, and to cure the disease if possible; full often to profess or to do more than this is beyond his art.

RICHARD QUAIN.

### DISEASE, Symptoms and Signs of.

When disease affects any of the functions or structures of the body it produces certain altered actions or changes, which, when observed during life, become evidences of its presence and often of its nature, and which then are called the symptoms and signs of disease.

The terms *symptom* and *sign* are often used synonymously, though the derivations of the words are by no means the same. *Symptom*, according to its derivation (*σύμπτωμα* = a coincidence), means simply a *coincidence*; that is to say, it coincides with the presence of certain phenomena. The term *sign* (from *signum*) is more distinctive, and seems more directly to point to some special or peculiar condition. Recently, however, an attempt has been made to give a more special meaning to these terms. *Symptom*, more especially if it be characterised by the prefix *vital*, is intended to refer to modifications of functions, or to such *subjective* phenomena as we can learn from the patient's account of his feelings. On the other hand, the term *sign*, more markedly with the prefix *physical*, indicates those morbid changes which are *objective*, or may be recognised by the senses of the physician, assisted by other appliances.

It would possibly be well if the meanings of the words—symptoms and signs of disease—as above stated, were to come into general use; but there are many difficulties in the way. For example, if the ear be applied to the chest in the case of incompetence of the aortic valves, we hear a murmur, and we say that there are 'physical signs' of aortic valve imperfection; but the locomotive pulse, and its peculiar beat, would by many be called a 'symptom' of incompetence of the aortic

valves. It is therefore extremely difficult to draw the distinction between the terms 'symptom' and 'sign.'

By whatever name these phenomena may be called, we must rely upon them as the chief means by which we are enabled to form our diagnosis. The more accurate and complete our knowledge of the functions of the body and of its component parts, and the more capable we are of interpreting, with all the completeness possible, the changes produced by disease, the more accurate will be our diagnosis as to its presence and its nature. How these phenomena may be best observed will be found discussed under the articles on DISEASE, Diagnosis of; and PHYSICAL EXAMINATION.

RICHARD QUAIN.

**DISEASE, Terminations of.**—The terminations of a disease must be regarded both from a *pathological* and from a *clinical* point of view.

Each *pathological* process or condition has modes of ending peculiar to itself, but it is beyond the province of this article to discuss these at any length, and one or two illustrations must suffice. Thus inflammation may terminate by resolution; by the formation of different effusions or exudations; or by causing suppuration, softening, induration, ulceration, or gangrene. Fever, if it end favourably, may terminate by crisis, lysis, or a combination of these modes, or in an irregular fashion. An effusion of blood may remain, more or less altered; may become organised; may soften and undergo a puriform change; may form a cyst; or may be altogether absorbed.

The *clinical* terminations of diseases are highly important, and demand more consideration. In the first place, a disease frequently terminates in the *death* of the patient. This event may take place suddenly or very rapidly, from the occurrence of some serious lesion, or of grave functional disorder of an organ essential for carrying on the phenomena which constitute life. In other cases death is the termination of a more or less acute illness, either affecting a person previously in the enjoyment of good health; or, what is not uncommon, being the consummation of a chronic malady, which has existed for a longer or shorter period. In still other instances, death is a slow and chronic process, the patient gradually sinking, several causes and morbid conditions often ultimately contributing to the fatal event. The modes in which death occurs are described elsewhere, and therefore need not be discussed in this article. See DEATH, Modes of.

In the next place, a large proportion of cases of disease end in *complete* and *entire* recovery, the patients being restored to their previous state of health, and no organic mischief remaining. This result may be ex-

pected in most of the ailments or functional disorders which are of such common occurrence, provided proper treatment is carried out. Again, the great majority of cases of acute disease terminate in complete recovery, taking them in the mass, though several affections of this class, when they do not prove fatal, are liable to leave behind more or less serious deterioration of the general health, or even actual organic disease. In this class of cases, when recovery does ensue, it is usually only after a more or less prolonged period of convalescence. Chronic complaints, if they are of a structural nature, cannot in most instances end in complete recovery, although to all appearance the patient may often be quite restored to health. Even in these cases, however, an actual cure may sometimes be effected, and that after a disease has had a prolonged duration. This is illustrated by several chronic skin-affections, syphilis, and chronic inflammation of mucous surfaces. Or it may happen that the patient recovers perfectly, only with the destruction of some structure which is not essential to life, such as a group of lymphatic glands.

Thirdly, *partial* or *incomplete* recovery is a very common mode of termination. This is observed in many cases of acute disease, where either the patient remains permanently in a state of general ill-health, without any actual structural lesion being discoverable; or some positive organic affection has been established, of which phthisis remaining after acute pneumonia, or cardiac disease following acute rheumatism, afford apt illustrations. An attack of an acute malady may also serve to bring out some latent constitutional predisposition; or may leave the patient in such a condition that certain so-called constitutional maladies are readily originated from slight causes. Partial recovery, amounting often to very marked improvement, may take place in many serious diseases of a chronic nature. This is illustrated by numerous cases of pulmonary consumption, in which disease great improvement is often observed, not only as regards the symptoms, but also in the local lesions, so much so that patients not uncommonly regard themselves as cured. Again, there are some complaints in which apparent recovery is brought about, but a tendency to recurrence remains, either without any obvious reason or from slight causes. Such affections are exemplified by ague, asthma, neuralgia, intestinal catarrh, bronchitis, and certain skin-diseases. As instances of incomplete recovery may be also mentioned the cure of some prominent symptom or symptoms, while the disease which originates these phenomena continues unaltered. Thus, it may be possible to get rid of ascites, which the patient regards as the disease from which he suffers, while cirrhosis of the liver, upon which the ascites depends,

is a permanent condition; extensive dropsy and other symptoms associated with cardiac disease may also be got rid of, while the organic mischief still remains. Sudden lesions may terminate in partial recovery. For instance, a case in which a sudden hæmorrhage into the brain has occurred, attended with marked apoplectic and paralytic symptoms, not uncommonly improves remarkably in course of time, the clot being more or less absorbed. Some complaints, which are usually sudden in their onset, may apparently be recovered from completely, but sometimes set up conditions which ultimately lead to permanent disease. Thus the passage of a gall-stone or of a renal calculus may excite such irritation as to cause an inflammatory process to be set up, which may induce permanent mischief, such as closure of the bile-duct or of the ureter in the several instances, and the effects may not be perceptible until a considerable interval has elapsed.

Lastly, it must be remarked that some affections can hardly be said to have any termination. They continue during the life of the individual, perhaps interfering but little or not at all with the health, or at all events not in any way contributing to the death of the patient, when that event does happen. This applies to many of the ailments from which people suffer; as well as to many chronic organic diseases not in themselves serious or giving rise to any important symptoms, and not implicating structures essential to life.

FREDERICK T. ROBERTS.

**DISEASE, Treatment of.**—This term has reference to the means by which disease may be prevented—*prophylactic* or *preventive* treatment; or its effects counteracted when it occurs—*remedial* or *curative* treatment.

1. **Preventive Treatment** will be found discussed under the heads—**CONTAGION; CLIMATE; DISEASE, Causes of; DISINFECTION; MALARIA; PERSONAL HEALTH; PUBLIC HEALTH; VACCINATION, &c.**; as well as in the several articles treating of special diseases. It is therefore unnecessary to say more upon the subject in this place.

2. **Curative Treatment.**—Bearing in mind that disease is a deviation from health in the functions or component materials of the body, it must be remembered that there is in organised bodies a tendency to maintain their healthy function and structure, and in case of disease or injury to resume it. This is especially manifest in the lower types of animals, many of which when mutilated are capable of resuming more or less completely their original form, to the extent even of the restoration of lost parts. In man and the higher animals this power of complete restoration is confined to the elementary cells and least complex structures

of which the body consists; the more complex tissues are not reproduced, nor are lost parts restored. There is, however, in man, as in all organised beings, a tendency to rectify deviations from health, and to restore the organisation to its normal condition. To remove or subdue the causes of disease, and to aid this restorative power in the establishment of healthy function and structure, is for the cure of disease the most philosophical indication that can be adopted. But our knowledge of disease and of remedial agents is not sufficient to enable us always to carry out these principles. As the treatment of disease has been directed sometimes to the one object and sometimes to the other, frequently to neither, it has given origin to a great variety of systems or methods of practice. Thus in the earliest history of the healing art, means the most diverse were used for the relief of suffering. Sometimes the suffering or the disease yielded whilst these means were being employed; and it was concluded, on very insufficient grounds, that these agents had 'cured' the disease. Persons who had felt, as they supposed, the beneficial effects of these particular remedies, communicated them to others as the result of their experience; and thus was established what has been known in Medicine as—

*Empiricism.*—This mode of practice has its advantages and its disadvantages. When aided by accurate knowledge and discrimination it often leads to satisfactory results; and many remedies suggested by experience, and that alone, are now found to be in accord with our more advanced scientific knowledge; take, for example, the use of mercury in syphilis, which, though long used empirically, is now known to act by its control over the nutrition of young cellular growths. So also with respect to quinine and other remedies of now established usefulness. On the other hand, mere empiricism, when vaguely applied, taints and damages to this day the treatment of disease. It is this practice which, for example, suggests opium to quiet a cough or a colic, without reference to the cause of the one or the other, and when an expectorant or a purgative would have been the suitable remedy; and it is this empiricism which does such harm in the hands of amateur practitioners, leading them to recommend for the relief of symptoms, remedies which they supposed had relieved like symptoms in other cases, however different the real nature or causes of these symptoms may have been.

*Rational treatment.*—On the other hand, modern science endeavours to take cognisance of the nature of disease, and also of the specific action of remedies; it seeks to counteract the operation of the one by the influence of the other. This constitutes the rational treatment of disease. To extend this system should be the object of the scientific practitioner. On

the one side, it is his duty to study the nature of disease itself, its causes, and their effects; on the other, to study the action of various agents on the living body in health and in disease; and, if possible, to trace how far the one is capable of combating and subduing the other. This study of scientific therapeutics is of comparatively recent date, and is now pursued with great zeal. The results already arrived at are alike satisfactory and encouraging. As rational treatment becomes more firmly established, scientific medicine will take a more elevated and nobler position. The modes or methods by which the two great principles just alluded to, the foundations as they are of the healing art, have been applied are extremely various, and, although these different methods may be traced to the one or to the other, they have received distinctive names, according as they are marked by some special characteristic. A few of these modes of treatment may be briefly enumerated.

1. *Expectant treatment* is founded on the principle that the restorative power of nature should be allowed entire freedom of action, the practitioner neither assisting nor interfering with its operation.

2. What is called *homœopathic treatment* would by some persons be included under the preceding head. It proposes to treat disease by giving in infinitesimal doses substances that are supposed to be capable of producing a diseased condition like that which they are intended to cure. It may be described in the words of Molière, who wrote long before Hahnemann, the inventor of homœopathy, as *l'art d'amuser le malade pendant que la nature guérit*. There is no doubt that in this and in similar methods of treatment, the imagination plays an active and useful part.

3. *Palliative treatment* consists simply in the adoption of means which are calculated to soothe, and to lessen suffering, and thereby to prolong life when the cure of disease is not possible.

4. *Stimulant treatment* is founded on a doctrine which regards most forms of disease as associated with or dependent on a lowered state of the vital powers, and which teaches that in such cases the free use of stimulants is the practice most to be relied on. See **STIMULANTS**.

5. *Antiphlogistic treatment* is the opposite of the preceding. It recognises in many forms of disease increased nervous excitement and vascular fulness, which are to be remedied by depressing agencies, such as low diet, bleeding, purgation, &c. See **BLOOD**, **Abstraction of**; and **DEPLETION**.

6. *Purgative, diaphoretic*, or otherwise *eliminative* treatment aims at removing by the intestinal mucous membrane, by the skin, or by the secreting glands, respectively, certain morbid matters; and thus allowing the re-

storative power of the system to operate more efficiently. See **PURGATIVES**, &c.

7. The *Water cure*, including baths, acts partly on the principle of elimination, partly by exerting a tonic influence. See **BATHS**; and **HYDRO-THERAPEUTICS**.

8. *Revulsive treatment* acts by producing counter-irritation by means of blisters, setons, issues, and the like. See **COUNTER-IRRITANTS**; **REVULSENTS**, &c.

9. *Antiseptic treatment* aims at destroying the germs of disease, whether on the surface of, or within, the body. See **ANTISEPTIC TREATMENT**; and **DISINFECTION**.

10. *Dietetic treatment* constitutes a greater or less portion of all modes of treatment. It implies a reference to the kind of food which is adapted to the circumstances in which the patient is placed, and which is suitable in the disease from which he is suffering. See **DIET**.

11. The treatment by *climate* operates more or less by removing the patient beyond the region of noxious influences, and placing him in circumstances which promote healthy action of the several functions.

It is well known that under these several and varied modes of treatment disease may yield and patients may get well. Hence it has been said that, as different means are made use of to obtain a single result, the treatment of disease can never be absolutely scientific. Phthisis is pointed to, for example, as a disease which one person seeks to relieve by cod-liver oil, another by climate, a third by tonics, a fourth by sedatives, a fifth by attention to the digestive organs, and a sixth by counter-irritation. We need scarcely say that the disease bearing the name of phthisis is an aggregate of phenomena or conditions, the relief of any one of which may lead to the amelioration of the others. Thus the general health might be improved by climate, and with it all the other symptoms. Cod-liver oil, with remedies calculated to improve the digestion, may lead to healthy nutrition, and thus to a mitigation of all the symptoms. The like remark applies to the other agencies mentioned. The treatment of disease must not, then, be condemned as unscientific because it cannot remedy a variety of morbid states by a single agent, but would aim, on still strictly scientific principles, by different agencies to overcome disease, the effects of which are manifested in different forms.

In conclusion, it may be repeated that the end and aim of the practitioner should be, if possible, firstly, to discover the cause or causes on which the disease depends, and to remove or counteract them if practicable; and, secondly, to endeavour, by every available means, to restore to health the functions of the body, and with that object to guide and assist Nature, but never to thwart her operations.

RICHARD QUAIN.

**DISEASES, Types and Varieties of.**—In the case of many diseases more or less distinct *varieties* are recognised, which in some instances constitute well-defined *types*. It is important to understand the precise significance of these terms in different cases.

In the first place the varieties of a particular affection may be founded upon diversities observed in its *clinical history*. Thus, according to the intensity of the symptoms and their duration, a large number of complaints are, as has already been pointed out, divided into acute, sub-acute, and chronic varieties. Again, many diseases, while presenting in the majority of cases a certain group of symptoms, upon which their general clinical description is founded, exhibit striking differences in the exact nature of the phenomena observed, as well as in their gravity, when the mass of cases is taken into account, and on these differences *varieties* or *types* are founded. This is well-exemplified by some of the acute specific fevers, such as typhoid fever, scarlatina, measles, and small-pox. Of these affections several varieties are described, dependent upon the severity of the symptoms, the nature of those which are most prominent, or the characters of the eruption.

In the next place, the classification of a disease into varieties may be founded upon a *pathological* basis. For instance, pulmonary phthisis may, in the writer's opinion, arise from different morbid processes, and many attempts have been made to arrange the cases of this disease into corresponding groups. Illustrations of these pathological varieties are also found in the different forms of cancer; in the varieties of pneumonia, of laryngitis, and of fatty disease of the heart; and in the classification of serous inflammations according to their morbid products, such as fibrinous, serous, purulent, &c. Again, such a pathological condition as dropsy or fever may be divided into varieties. Thus dropsy is arranged according to its situation and distribution, as anasarca, ascites, &c.; or according to its pathological cause, whether cardiac, pulmonary, hepatic, &c. Fever is recognised as having several important types, founded upon its intensity, its course, and the exact nature of the phenomena accompanying the pyrexial state.

Another division of a disease into varieties is *ætiological*, the cases being grouped according to their causation, either the immediate pathological or the more remote exciting causes being employed as the basis of division. Thus we have the different forms of meningitis (simple, tubercular, rheumatic, &c.); the ætiological varieties of pleurisy or peritonitis (idiopathic, traumatic, perforative, tubercular, secondary, &c.); those of joint-inflammation (simple, rheumatic, gouty, serofulous, &c.); or those of intestinal obstruction. Ætiological varieties are often at

the same time characterised by differences in the pathological results and products.

Lastly, it must be mentioned that sometimes a certain *group of symptoms* is summed up for convenience under some single term, which symptoms really depend upon very different morbid conditions and causes; and therefore it often becomes necessary to classify affections thus named into varieties. Dyspepsia, neuralgia, apoplexy, epilepsy, and paralysis will afford illustrations of such an arrangement.

FREDERICK T. ROBERTS.

**DISINFECTION.**—SYNON.: Fr. *Désinfection*; Ger. *Desinficieren*.

**DEFINITION.**—Disinfection, in the proper sense of the term, means any process by which the contagium of a given disease may be destroyed or be rendered inert.

Disinfectants, however, are used in practice for several objects, and in consequence the term has often been vaguely applied to the use of heat or chemical means for preventing the generation or for the destruction of noxious agents, whether products of specific disease or not. In this vague and erroneous sense disinfectants have been confounded with *deodorants*, which merely cover or destroy offensive odours without affecting the contagia; and with *antiseptics*, which 'are fatal to the growth and multiplication of microzymes.' Following the line indicated by the late Dr. Baxter in his valuable report on an experimental study of certain disinfectants, it is necessary to distinguish—

1. The true meaning of the word—that of acting on the specific poisons of communicable diseases in such a way as prevents their spreading.

2. That of acting upon organic substances in such a way as renders them less liable to undergo molecular change and decomposition, whether spontaneously or under the influence of catalytic agents, as in the case of emulsin upon amygdalin; or under the influence of living organisms, such as are connected with fermentation and putrefaction. Examples of this kind of action are seen in salting meat, and in preserving small animals in weak solutions of carbolic acid.

3. That of preventing or arresting decomposition by killing the torulæ associated with fermentation in slightly acid media, or the bacteroid organisms associated with putrefaction in neutral or alkaline media. Properly speaking, this is the action of an antiseptic, but the relative power of disinfectants has been largely estimated by their efficacy in this respect—partly, no doubt, because antiseptic power is desirable in a disinfectant, but chiefly because it is so difficult to submit disinfectants to their proper test by experimenting upon contagium. Recent experiments upon inhibition of growth of pathogenic bacteria show that mercuric chloride,

allyl alcohol, oil of mustard, and certain other ethereal oils prevent the growth of anthrax bacilli in extreme dilution. Quinine, two parts per thousand, prevents the development of anthrax bacilli or that of the spirochæta of relapsing fever.

4. That of the destruction of the noxious products of the metabolism of dead organic matter, however brought about. These products consist chiefly of gases or vapours, many of which, such as sulphuretted hydrogen, ammonia, and sulphide of ammonium, are easily destroyed by appropriate agents, even when used in a very dilute state; and success in this respect is no proof of the value of a disinfectant in its true sense, though the power of destroying such emanations is possessed by almost all disinfectants of practical utility.

GENERAL REMARKS.—It has been proved that the contagia of several diseases must consist of minute solid particles, for they are neither soluble, nor diffusible, nor volatile; they can be seen with the microscope, and can be cultivated out of the body; and we may infer that all other contagia are particulate likewise. A characteristic of contagium, due to its particulate nature, is that dilution lessens the chance of infection, but has little effect upon the case if the disease be taken. There is either no effect at all, or a full specific effect. Contagium particles are apt to exist as clouds in air, water, or milk, instead of being equally distributed throughout; and this bears upon practical disinfection. The particulate and non-gaseous form of contagium floating in the atmosphere prevents it from being absorbed by any liquid or solid disinfectant which does not wash or come into intimate contact with every portion of the air, and as this is impracticable, infected air can only be purified by gaseous disinfectants, such as sulphurous acid or chlorine. Disinfectants of this kind, to be effective, must be present in such a quantity as is incompatible with the existence of human beings. From this it follows that saucers of disinfecting fluids, or irritating vapours and gases in the sick-room, are merely a useless annoyance to the patient, except in so far as they may be desired as deodorants. The best method for dealing with infected air is to replace it by ventilation, especially by means of *ventilating* open fire-places. The proper use of volatile disinfectants is the purification of walls, ceilings, and inaccessible places; and for this purpose, if possible, enough should be used to saturate the atmosphere, remembering that the virulent particles are most likely protected by being buried in a bit of epithelium or surrounded by an albuminous envelope.<sup>1</sup>

<sup>1</sup> Though disinfectant or antiseptic gases of such strength as can be tolerated in the sick-room are utterly inept as regards useful effect upon contagium, it is just possible that they may be of service in

The nature of the medium in which contagious particles are suspended has the most important bearing upon the selection of a disinfectant. The presence of albumen is found to protect septic germs to a considerable extent against the action of permanganate of potassium and chlorine, but has little or no influence upon the action of sulphurous acid and carbolic acid. A striking instance of this was noticed by Schill and Fischer, who found that fresh tubercular sputum containing bacilli and spores was not disinfected in twenty-four hours by an equal volume of solution of mercuric chloride 1 in 500, though an equal volume of 5 per cent. carbolic acid solution accomplished the disinfection in that time. This possibly explains in part the contradictory results obtained from experiments with disinfectants, and also shows the necessity of thoroughly mixing disinfectants with liquids or substances to be disinfected.

Some pathogenic organisms, such as the bacilli of anthrax, are very easily killed, while others, such as the spores of the same bacilli, are extremely resistant. It is possible that in many cases the contagium may be of a species or at a stage when it can be readily destroyed by a feeble disinfectant, but in the absence of knowledge prudence requires the opposite assumption.

A cardinal principle in disinfection is that it should be carried out at the source, or as near the source, of the contagion as possible. Inunction with lard, with carbolised oil (1 to 40), or with glycerine, to clog epithelial scales, and regular washing and change of clothing, will do much to protect the purity of the air against contagium proceeding from the skin in such diseases as scarlet fever and small-pox. One part of ethereal solution of peroxide of hydrogen to eight parts of lard is an excellent application for the skin in typhus. Discharges from the mouth, nose, and bowels, as well as the urine, should be received in vessels containing disinfecting solutions to cover them and give protection to the air; and then larger quantities, or more concentrated solutions, as the case may be, should be thoroughly incorporated with the discharges before they are removed from the original vessels.

Of all agencies for preventing the spread of communicable disease, cleanliness is one of the most important. Facts have been adduced pointing to the conclusion that filth, when undergoing change of a fermentative or putrefactive nature, is in a condition the most conducive to the extension of infectious

destroying or rendering incapable of change the organic matters evolved from the skin and lungs, which are always very noxious, and may be especially so in disease. These organic matters are necessarily more or less re-breathed unless the patient be placed in a current of air. If ventilation sufficient to prevent all odour cannot be provided, then some gas, such as chlorine or ozone, that will destroy the cause of the odour, is certainly desirable.

disease. This is probably explained by the rapid multiplication of any specific disease-organisms contained in the filth. Pending the removal of accumulations of dirt, and for the protection of workmen, fermentation may be delayed by the application of crude carbolic acid, or solution of mercuric chloride.

The ultimate fate of contagium is to be destroyed by putrefaction, and this appears invariably to destroy its specific infective power. In certain cases where real disinfection is impracticable, as in dealing with the accumulation of manure and litter from a number of animals suffering from cattle-plague, the natural processes may be hastened by stacking the material so that it shall 'heat,' or may even be destroyed by spontaneous combustion. Certainly putrefaction should not be delayed by small additions of disinfectants, which cannot accomplish the destruction of all noxious matter present.

**SPECIAL DISINFECTANTS.—1. Heat.**—Heat, dry or moist, is perhaps the best disinfectant we possess. High temperature and length of exposure are, to a certain extent, mutually compensatory, but it appears that a temperature below 140° F. (60° C.) will not disinfect vaccine even with long exposure. Tyndall points out that some germs seem to be in a dormant condition, in which they resist the action of heat unless applied very long or intermittently, so as to start their vitality into growth, when they are easily killed. Disinfection by dry heat (which is, however, best for the destruction of insect vermin) is now being superseded by steam. Dry heat penetrates so slowly into fabrics that they are injured before a disinfecting temperature is attained throughout. The presence of moisture assists the action of hot air, as it likewise does that of gaseous SO<sub>2</sub> and Cl. Koch found that 1½ hour's exposure within test-tubes in an oven containing air saturated with moisture at a temperature from 230° F. to 245° F. destroyed sporeless micro-organisms and spores of fungi, but did not affect spores of the bacilli of potato, hay, and anthrax, nor the spores of garden earth. These were all destroyed by three hours' exposure to 284° F. A current of steam at 212° F. destroyed spores of earth, anthrax, and tubercle-bacilli in less than fifteen minutes, when they were freely exposed. Steam penetrates clothing quickly, but may take some time to raise the temperature of sheltered articles, especially if wet. Modern steam-disinfectors are made with a jacket space to which live steam may be admitted, so that the internal chamber may be used as a simple hot-air chamber where steam is not admitted directly to it. With a proper apparatus the articles come out dry. Steam instantly ruins leather, and fixes permanently any stains of blood or discharges. Stained clothing should be previously soaked in cold water and the water afterwards disinfected by mercuric chloride.

It has been abundantly proved that ordinary boiling and washing will completely disinfect the linen of a fever hospital. The water should attain the full temperature of 212° F.

Nearly all the chemical agents used in disinfection are mutually incompatible, and therefore only one should be used at a time.

**2. Carbolic Acid.**—A solution of this substance of the strength of 5 per cent., or 1 in 20, is the only one fit for use in disinfection. For steeping fine clothing a solution should be made from crystals. The solution generally useful is that obtained by making up one gallon of crude 80 per cent. acid to sixteen gallons with water. The results of the experiments of Baxter and others prove that 'no virulent liquid can be considered disinfected by carbolic acid unless it contain at least 2 per cent. by weight of the pure acid.' More recent experiments show that in some cases this proportion of carbolic acid is not nearly enough. Anthrax spores required to soak over twenty-four hours in 5 per cent. carbolic solution to be destroyed, though blood containing anthrax bacilli was almost instantly sterilised by a 1 per cent. solution. With our present knowledge it would be safer to employ stronger acid, or in any case to use a large quantity of 5 per cent. Combinations of carbolic acid are greatly inferior to the pure acid, and its solutions in oil and alcohol are found to be absolutely inert. Thymol and salicylic acid are affected in the same way by solution in oil. Judging from the light of experiments, carbolic acid vapour is quite useless. Very small quantities of the liquid acid mixed with organic fluids enable them to remain fresh and resist decay for a long time. So little as one-fifth per cent. preserves milk. It is obvious then that small quantities of this disinfectant, instead of destroying contagium, may actually preserve its activity, when otherwise it would have succumbed to the action of natural agencies. This danger may accompany the limited use of any disinfectant that has a 'pickling' or preservative action in small quantity. Owing partly to the volatility of carbolic acid, which removes it in time, and partly to the peculiarity of its action, another danger attends its use in anything short of full strength and large quantity when applied to kill contagium. The acid may, for a time, deprive the contagium of its infective power without permanently abolishing it, and the virulent properties may be regained whenever the acid has evaporated. This has been proved experimentally by Dr. Dougall, of Glasgow, who found that vaccine mixed with carbolic acid (1 in 50) *regained* its infective power after 10 days' exposure to the air.

For removing odour from the hands after working in the dissecting-room, a 1 per cent. solution of carbolic acid is superior in efficacy

to permanganate of potassium, even when strong enough to stain the skin, and is also preferable to chlorinated lime.

**3. Sulphur Dioxide.**—The aqueous solution of this substance contains sulphurous acid. It destroys sulphuretted hydrogen thus,  $\text{SO}_2 + 2\text{H}_2\text{S} = 2\text{H}_2\text{O} + \text{S}_3$ , and combines with ammonia. For aerial disinfection the best plan is simply to burn sulphur in very large quantities. Even in presence of abundant moisture, Koch pronounces  $\text{SO}_2$  useless for practical disinfection. By volume, 10·5 per cent. of the gas in a room failed to affect spores of anthrax, &c., in twenty-four hours, whether wet or dry. About 3 per cent. in forty-eight hours had not destroyed the vitality of micrococcus prodigiosus, pink yeast, or bacteria of blue pus. In an ordinary room a gaseous disinfectant rapidly disappears. On the other hand, Cyrus Edson tries, from the statistics of the Health Department, N.Y., to prove the efficacy of  $\text{SO}_2$  fumigation (3 lbs. sulphur to 1,000 cubic feet) in small-pox, scarlet fever, and to a less extent in measles and diphtheria-infected houses. The statistics are not convincing to the present writer. Sulphur dioxide destroys the activity of dry vaccine on points very rapidly, and even when much diluted stops the amoeboid movements of living cells, kills vibrios, and acts deleteriously on vegetation. Sulphur dioxide preserves meat and other substances, when in closed vessels, for very long periods. It bleaches vegetable colours, attacks iron, and is absorbed by cloth and leather—facts to be remembered in practical disinfection. 1 lb. of sulphur, when burned, produces 11·7 cubic feet of sulphur dioxide gas.

**4. Chlorine.**—Chlorine is most easily obtained from 'chloride of lime' or bleaching powder, by adding hydrochloric or sulphuric acid. Exact proportions cannot be stated, as the value of the bleaching powders varies; but rather more acid than of the equal parts of bleaching powder and strong hydrochloric acid may be taken. The acid should be diluted before use. For deodorising water-closets, some crystals of potassium chlorate may be thrown into a wide-mouthed bottle containing dilute hydrochloric acid. Euchlorine comes off gradually, and is both more effective and more agreeable than chlorine. The most marked character of chlorine is its strong affinity for hydrogen, which enables it to break up compounds containing that body, and to set free in a nascent or active state the oxygen combined with hydrogen in water. It is, therefore, one of the most universally applicable and powerful deodorisers in existence. When merely used as a deodoriser, enough euchlorine may be expelled from moist 'chloride of lime' by the carbonic acid of the air for most purposes. In air saturated with moisture 0·3 per cent. chlorine kills all minor organisms that are freely exposed; but any cover, such as a piece of

blotting-paper, prevents the result. Less moisture demands 1 per cent. chlorine.

**5. Permanganate of Potassium.**—This substance is non-poisonous, and is a good deodorant, especially for the emanations from organic bodies. It is, moreover, free from odour, and its aqueous solution shows, by loss of colour, when it is exhausted. It is a very suitable deodorant for the sick-room, as, when dissolved in water and a large surface of the solution exposed to the air, it will absorb gases to some extent. Contagium, being non-gaseous, is not affected, unless in contact with the solution. Permanganate of potassium is a true disinfectant, oxidising and destroying contagia as well as putrid matters; but the quantity required and the price render its use almost impossible, for enough permanganate has to be used to destroy the medium or vehicle bearing contagium as well as the contagium itself. The solution should contain 5 per cent. permanganate after all chemical action has subsided. Condy's fluid is a solution of this substance in water. When the virulent liquid or matters are small in quantity, permanganate solution forms a capital recipient, and may stand by the bedside as a deodorant till required as a disinfectant. Permanganate has no effect in restraining the appearance of bacteria, or preventing the onset of putrefaction.

**6. Acids.**—The mineral acids and glacial acetic acid have all disinfecting power when used in sufficient quantity for a long time, but there are serious difficulties in the way of their use. HCl, 2 per cent. in solution, required ten days to kill anthrax spores.

**7. Nitrous Acid.**—Nitrous acid can be easily disengaged as a gas by putting bits of copper into nitric acid, or pouring nitric acid upon sawdust or starch. It is the best deodorant for the deadhouse, and, without doubt, it is a disinfectant, but it is too dangerous for ordinary use, as it may easily be breathed in quantity sufficient to cause fatal bronchitis.

**8. Chlorinated Lime.**—Bleaching-powder, commonly known as 'chloride of lime,' gives off chlorine easily, and this probably explains its disinfecting power. It is very cheap and manageable, and hence of much importance.

**9. Quicklime.**—Liberius Kitasato and Pfuhl, confirmed by Drs. Richard and Chantemesse, state that fresh excreta of cholera, enteric fever, and dysentery are sterilised, and the bacilli destroyed, so that the stools are disinfected, by 2 per cent. of a 20 per cent. fresh milk of lime in a few hours. The experiments detailed are not conclusive to the writer as to real disinfection in all cases. Quicklime is so cheap and abundant, that it could be used in any quantity. It is soluble in water in the proportion of only 1 in about 700.

10. **Mercuric Chloride.**—*Perchloride of Mercury, Corrosive Sublimate, Malleus Metallorum*, the most powerful chemical disinfectant known, dissolves in 16 parts of cold water, is extremely poisonous, and corrodes metals. With albuminous matters it forms insoluble precipitates, which are prevented by addition of common salt, HCl, or tartaric acid. Precipitates must be prevented where disinfection has to be repeated, as they might be dangerous. The solution with tartaric acid is not stable, and should be freshly made. A spray of 1 in 1,000, or washing with 1 in 5,000, killed the most resistant organisms in ten minutes. Enough should be used to leave 1 in 5,000 after any HgCl<sub>2</sub> is precipitated by sulphur or albumen. After disinfection is finished, copious washing with water removes the remaining mercury salt. For utensils, clothing, &c., 1 in 2,000, and for excreta an equal bulk of 1 in 1,000 solution, are recommended.

In regard to the agents hitherto considered, we have more or less of the sure light of direct experiment upon contagium; but the claims of the following and a legion of other substances asserted to be 'powerful disinfectants, of which it is impossible to speak too highly,' rest entirely upon chemical theories, or the opinions of physicians, or upon their power of coagulating albumen, or of delaying or preventing putrefaction and fermentation, or of deodorising. It will be scarcely necessary to do more than enumerate the best, as follows:—

11. **Metallic Salts.**—Metallic salts include—(a) *Bichromate of potassium*. (b) *Sulphate of copper*. (c) *Chloride of zinc*. A 5 per cent. solution had no effect on anthrax spores in a month, and 1 per cent. failed to kill micrococcus prodigiosus in forty-eight hours. (d) *Chloride of aluminium*. (e) *Ferric chloride*, which, if strong, liberates offensive fumes from animal matters, but is a fair antiseptic and preservative. (f) *Ferrous sulphate*. (g) *The waste chlorides*, from the manufacture of chlorine, contain MnCl<sub>2</sub>, Fe<sub>2</sub>Cl<sub>6</sub>, and free HCl, which cost next to nothing, and might be used for larger masses of filth or drains.

12. **Ozone.**—This body, got by half-immersing a stick of phosphorus in tepid water, or by mixing gradually 3 parts of strong sulphuric acid and 2 parts permanganate of potassium, oxidises organic matter, and so destroys odours. Terebene and cupralum, a preparation containing terebene, are good deodorants, and give rise to ozone.

13. **Charcoal.**—Charcoal condenses gases within its pores, where combustible gases are destroyed by the condensed oxygen. Contagium, unless in water, does not enter the pores, for, being particulate, it is not absorbed from the air as gases are.

**PRACTICAL DISINFECTION.**—In conclusion, a few remarks may be offered as to the modes of carrying out disinfection under

circumstances in which it is commonly required.

1. **Clothing and Bedding.**—In dealing with the ragged and worthless articles of the poor, local authorities will generally find it most satisfactory to both parties to burn them and replace them with new. By such discreet generosity danger is averted, and goodwill created, which helps in getting early information and carrying out measures, and so, by shortening epidemics, saves expense. If not burned, clothing may be steamed as described under *Heat*, or well boiled with soda. Before coming to the washhouse they may be steeped in 5 per cent. carbolic solution, or perchloride of mercury (1 in 2,000), or chlorinated lime (2 oz. to the gallon).

2. **Rooms.**—The essential process for disinfecting rooms is thorough cleansing with soft soap and hot water, which may contain 5 per cent. carbolic acid, but the carbolic solution is not so easily handled. The walls and ceiling should be brushed, and wall-paper removed. Furniture, if iron—a bedstead for example—is to be taken down and washed with carbolic solution, and removed from the room, or smeared with vaseline if to be fumigated. Textile fabrics should be steamed or boiled, or spread out in the room for fumigation; but this is not so effective, and colours are bleached. Should it be considered desirable to fumigate, the room should be steamed for some hours. The chimney, doors, and windows are to be closed, and crevices covered with paper pasted on. Then 15 lbs. chlorinated lime per 1,000 cubic feet, made into cream with water in shallow dishes, has 22 lbs. HCl added from vessels which tilt over as the operator escapes. The door is to be shut until next day, when the windows and doors are all to be opened, and kept open for twenty-four hours. In white-washed rooms the walls should be scraped, and then washed with hot lime in addition to the fumigation.

3. **Drains, Water-closets, &c.**—Proper drains remove sewage so swiftly and completely, that little or no sewage-gas is formed if ventilation is given. For bad drains carbolic acid, chloride of zinc, or waste chlorides from the manufacture of chlorine, are fair palliatives. The excreta from cases of infectious diseases require a very large quantity of disinfectant, which should be applied in a concentrated form before they are thrown into the water-closet or house-pipes. When a reliable amount of disinfectant is in these cases sent down the pipes, it is apt to corrode them unless it has been allowed to expend its energy on the excreta alone in the first place. If small quantities of disinfectants are poured down water-closets, it is better to mix them with the after-flush water which fills traps and basins, so that the little energy available may be devoted to the destruction of any slime adhering, or portions of organic matter retained. Permanganate

of potassium is the most pleasant agent for this purpose, though expensive. When there are no water-closets, the excreta, in cases of cholera and typhoid fever, should be received in a vessel containing half a pint or more of a 1-in-20 solution of commercial hydrochloric or sulphuric acid, and then put, along with some chlorinated lime, into a covered stoneware vessel in the back yard. After a few hours the contents of this vessel may be thrown into the cesspool or upon the midden.

**4. Dead Bodies.**—Dead bodies, if putrid or bearing contagium, should be wrapped in sheets wet with 1-in-20 carbolic solution, or 1-in-1,000 perchloride of mercury; or, if coffined, sawdust saturated with one of these solutions should be packed around them.

It is necessary clearly to keep in view the object desired when selecting disinfectants, deodorants, or antiseptics; whether it be destruction of contagium, merely 'pickling' and preserving, arresting putrefaction and fermentation, or deodorisation. From all that has been said it is evident that the different 'disinfecting' nostrums, applied as their inventors direct, can have little effect upon contagium, but may have more or less power in the other directions indicated.

**DISLOCATION OF ORGANS** (*dis*, apart; and *locus*, a place).—See ORGANS, Displacement of.

**DISPLACEMENT OF ORGANS.**  
See ORGANS, Displacement of.

**DISSECTION WOUNDS.** — See POST-MORTEM WOUNDS.

**DISTOMA.**—See ENTOZOA.

**DISTOMA RINGERI** vel **PULMONALE.**—Under this name the writer originally described in the *Medical Times and Gazette* (July 8, 1882) a species of fluke, the mature form of which inhabits the human lung, where it was first found in Formosa, by Dr. B. S. Ringer, in 1879. The ova of the parasite have frequently been found by Professor Baelz, of Tokio, by the writer, and by others, and by them are associated with a peculiar form of recurrent hæmoptysis, to which the term *endemic hæmoptysis* has been applied.

**SYMPTOMS AND PATHOLOGY.**—The symptoms of disease associated with the presence of the distoma Ringeri are a slight cough; the expectoration of a characteristic rusty-brown, viscid mucus; and at times hæmoptysis, slight or copious. The hæmorrhage occurs at irregular intervals during many years. The expectoration of rusty bronchial mucus is persistent, and in this the ova are readily discovered with the microscope. These are pale brown bodies ( $\frac{3}{500}$  in.  $\times$   $\frac{1}{500}$  in.), ovoid, double-outlined, operculated at the broad end, and containing protoplasmic globules having very active molecular movements. If the

sputum is occasionally shaken up in fresh water, there is developed in most of the ova, in the course of six weeks to two months, an active ciliated embryo which in time escapes by forcing back the operculum. It may be concluded from this that drinking-water, or a fresh-water animal acting as intermediary host, is the medium by which the disease passes from one human subject to another. See ENTOZOA.

This disease has hitherto been found only in Japan, Corea, and Formosa, but its distribution is probably much more extended.

The mature parasite measures from 8 to 10 mm. by 5 to 6 mm. It resides in cavities and burrows connected with the smaller bronchi, into which it discharges its ova. As many as twenty of these parasites have been found in one case.

**TREATMENT.**—Inhalations of sulphurous acid, sprays of turpentine, as well as koussou, quassia, and santonin, have been administered without much apparent benefit.

PATRICK MANSON.

**DIURESIS** ( $\delta\acute{\iota}\alpha$ , through; and  $\omicron\upsilon\rho\acute{\epsilon}\omega$ , I pass water).—A free excretion of urine, whether naturally or artificially induced. See DIURETICS.

**DIURETICS** ( $\delta\acute{\iota}\alpha$ , through; and  $\omicron\upsilon\rho\acute{\epsilon}\omega$ , I pass water).

**DEFINITION.**—Remedies which increase the secretion of urine.

**ENUMERATION.**—The following comprise the most important diuretics: Water; Milk; salts of Potassium, Sodium, and Lithium; Calomel; Alcohol, Nitrous Ether, solution of Ethyl Nitrite; Turpentine, Juniper, Copaiba; Cantharides; Digitalis, Strophanthus, Squill; Caffeine, Theobromine, and its compound with Salicylic Acid and Sodium termed 'Diuretin'; Tobacco; Scoparium, and Sparteine. The action of diuretics is often aided by brisk purgation, depletion, counter-irritation over the loins, and sometimes by the use of mercury.

**ACTION.**—The secretion of urine appears to consist partly of filtration of fluid through the glomeruli of the kidney, and partly of secretion by the cells of the urinary tubules. The amount of urine excreted depends on the rapidity with which the blood flows through the glomeruli, and this again depends on the height of the systemic blood-pressure and the dilatation or contraction of the renal arteries. The secretion is increased by anything which raises the blood-pressure throughout the system generally, or in the renal arteries locally. The systemic blood-pressure may be raised by cold to the surface, digitalis, squill, and tobacco. Digitalis, and possibly other drugs, have also a local action on the renal arteries, which are more readily affected by some drugs than other arteries in the body. Nitrous ether and solution of ethyl nitrite probably act as diuretics by dilating the

renal arteries. The exact mode of action of the other diuretics is not determined; but common salt, nitrate of potassium, urates, and urea increase the flow of urine even although the pressure in the vessels of the kidney is very low. It is therefore probable that they stimulate secretion by acting on the nerves or cells in the kidney itself; and probably caffeine acts in a similar manner.

USES.—Diuretics are employed to increase the flow of urine, and thus remove water or excrementitious products like urea from the body. They are used in cases of general dropsy, or of accumulation of fluid in the peritoneum or pleura. In febrile conditions they are given to aid in the elimination of waste matter. They are also employed in order to render the urine more watery, and thus prevent the deposition of solids from it, and the formation of calculi in the kidney or bladder, or to redissolve such concretions when they are already formed. Digitalis and squill are most useful in dropsy dependent on heart-disease; the other remedies are more effective in dropsy dependent on disease of the kidneys or liver. The action of digitalis and squill is greatly assisted by the addition of a little blue pill; and when the kidneys are much congested or pressed upon from without by accumulation of fluid in the abdominal cavity, diuretics sometimes fail to act until the congestion has been relieved by depletion from the loins or the use of a brisk purgative, and the pressure removed by paracentesis. See DROPSY.

**DOUCHE** (Fr.).—DEFINITION.—A jet of water propelled against some part of the body through a *doccia* or pipe. The size of the jet of water, the degree of its impetus, and its temperature can all be regulated. A douche differs from simple affusion in its application being more local, and the force with which it is applied being greater.

APPLICATION AND ACTION.—Douches of cold and of hot water, of vapour, and occasionally of gas, are employed; but those by far the most commonly used, except where there are hot natural waters, are of cold water.

The immediate effect produced by a cold douche on those who are unaccustomed to it is a feeling of shock, spasmodic shortness of

breathing, palpitation of the heart, and sometimes pain in the back of the head. Locally the first effect of a douche is to deaden the sensibility of the part to which it is applied; but if the douche be powerful enough, reaction of the part comes on in about forty seconds. This continues for a time; but if the douche be kept up for three or four minutes, the pulse falls seven or eight beats, the deadening of sensibility returns, and the temperature of the part is greatly lowered; when the douche is withdrawn, reaction again takes place. This alternate sedative and stimulating effect, producing emptiness and turgescence of the vessels, quickens the action of the capillaries of the part, and thus favours the transmutation of tissue. The mechanical effect of the force with which the douche is applied must not be overlooked. If great, it produces the highest amount of stimulation, which may almost amount to inflammation.

Different portions of the body have different degrees of tolerance of the douche. Thus the extremities and the head bear it better than the chest, and the chest somewhat better than the abdomen; and the posterior aspect of the body bears it much better than the anterior. Patients soon get accustomed to the cold. Warm douches produce less shock, and are more easily borne, but they are, comparatively speaking, little employed in private houses. An alternation of hot and cold douches, known somehow by the name of *Scotch*, is a valuable remedy; in it the hot water rapidly restores the irritability of the part deadened by the cold water, and there is a maximum of action and reaction of the part obtained. Under particular circumstances it may be expedient to use a jet of steam, but this, of course, must be done with caution; and a jet of carbonic acid is sometimes propelled against the eye or ear, or the neck of the uterus. So-called *ascending douches* are used for the rectum or the vagina. Douches for the eye and the ear have been used of late years. In a certain sense what the English call *pumping* is a variety of the douche, and the *shower-bath* is in reality merely a multiplication of fine douches. The action of douches is more or less general according to the portion of the body to which they are applied. Thus the application of a douche to the head has the most general action, and that to the spine the next. In either case it is impossible to limit it very strictly, and there is a certain amount of affusion besides the direct douche. A douche, again, applied to one of the extremities may easily be localised; and a douche may be applied only to one part or to several parts of the body in succession.

Douches merely require a pipe with nozzles of various sizes in connexion with a cistern at a certain elevation, or with a pumping machine; they can easily be improvised. Shower-baths can be procured with equal facility. A vapour-douche can be got by

attaching a pipe to a vessel of boiling water. In the case of fine douches used for the eye, the water is propelled with sufficient force by the action of a caoutchouc bag worked by the hand. Carbonic acid is practically little used, and only where there is an abundant natural supply of the gas.

Perhaps 50° F. may be considered the average temperature of a cold douche, and from four minutes to a quarter of an hour its average duration. The course of douching will probably extend at least over a fortnight. As to the actual temperature of the water, the sensation it produces in the patient depends most on his condition. Thus water of 45° F. may feel ice-cold to one who has just quitted a hot bath. In like manner a douche of slightly-heated water may appear quite warm when applied to a part cooled by a cold douche. The temperature of a douche should vary according to the condition of the patient.

USES.—As a general rule we may say that douches are only applicable in cases of chronic disease; that cold douches are most useful in constitutional diseases; and that warm douches, and the alternation of hot and cold, are most suitable in local affections. The use of hot and cold douches alternately has been much and successfully employed of late in France, for the treatment of certain nervous diseases.

The cold douche, when it is employed gradually and with judgment, is found serviceable in chlorotic and hysterical conditions, in hysterical paralysis, and in over-sensibility of the skin, with tendency to catch cold; and of late years it has formed a part of the special treatment of phthisis in elevated places. As cold affusion on the head is very serviceable in infantile convulsions, so the application of a douche of cold water to the head is a calmative and hypnotic in maniacal cases. It is, perhaps, not so much used in this way as formerly, because it has, like the shower-bath, come to be considered a sort of punishment to troublesome lunatics. Still it is a valuable agent. Hydropathic practitioners have found douches useful revulsives in congestion of the liver and of the uterus.

Locally douches have been used, but with moderate benefit only, in some cases of skin-affections and of chronic ulcers. Their principal local application, however, is in cases of old sprains, in chronic rheumatism or gouty thickenings of joints, in lumbago, in some neuralgias, and in paralysis when it is not too recent. The *Scotch* is far the most effective for these purposes, and there seems to be some evidence of its having been efficacious in threatened *tabes dorsalis*—certainly more efficacious than any other remedy. Douches might be used more extensively in private houses; still, as assistance is always required by the patient, public baths have advantages for their application.

**DROPSY** (ὕδρωψ: from ὕδωρ, water; and δψ, aspect, appearance).—SYNON.: Fr. *Hydropisie*; Ger. *Wassersucht*.

DEFINITION.—Accumulation of serous fluid in the subcutaneous cellular tissue, or in a serous cavity.

Dropsy is known by various other names, according to the portion of the body affected. When confined to the subcutaneous cellular tissue it is termed *oedema* or *anasarca*; to the peritoneal cavity, *ascites*. The term is often limited to these two forms of the disease; and exudations similar to that of ascites in other cavities are termed *hydropericardium*, *hydrocephalus*, *hydrocele*, *hydrops oculi*, *hydrops articuli*, and *hydrothorax* or *pleural effusion*, according as they are contained in the pericardium, arachnoid, tunica vaginalis, eye, joint, and pleural cavity respectively.

**PATHOLOGY**.—The accumulation of fluid in the tissues, or in a serous cavity, depends upon more fluid exuding from the blood-vessels than can be taken up by the absorbents. This condition may depend on an increase in the rapidity of exudation above the normal, or on a diminution in the absorption, or on both together. Increased exudation may be due to alteration (1) in the calibre of the arteries or capillaries; (2) in the condition of their walls; (3) in the condition of the blood; and (4) possibly also in the condition of the tissues. Diminished absorption is chiefly due to obstruction of the absorbents, although alteration in the tissues may also play a part. Obstruction may be (1) local or (2) general. So long as no obstruction to absorption occurs, it rarely happens that more fluid can exude from the blood-vessels than the absorbents can again take up. Absorption is partly carried on by the veins, and partly by the lymphatics; principally, however, by the veins. When venous obstruction takes place, fluid is apt to accumulate in that part of the body from which the blood ought to return by the obstructed vessel. But it does not always so

accumulate; for it may happen that the lymphatics are able to absorb all the fluid which exudes from the capillaries, and to return it into the general circulation. Thus it has been found by Ranvier that ligature of the vena cava in a dog does not usually produce œdema of the lower extremities, but if one sciatic nerve be divided in such an animal, the corresponding leg at once becomes œdematous. The reason of this is that, so long as the nerve is intact, the lymphatics can absorb all the fluid which exudes from the capillaries; but when the nerve is divided the arteries dilate, more fluid is poured out than the lymphatics can absorb, it accumulates in the tissues, and œdema ensues. This œdema is not due to paralysis of the limb, but to paralysis of the vessels. For if the sympathetic fibres through which the vaso-motor nerves pass to the sciatic nerve are divided before they join the motor fibres of that nerve in the sacral plexus, the power of movement remains unimpaired, but œdema occurs just as if the whole nerve had been divided. If, on the other hand, the motor strands of the sacral plexus are cut before they are joined by the sympathetic fibres, the limb is as completely paralysed as if the sciatic nerve had been cut, but no œdema takes place. Any obstruction to the venous flow will operate in the same way as ligature of a vein, though to a less extent, the effect varying according to the amount of obstruction. Thus regurgitation of blood through the tricuspid valve tends to produce general anasarca, and obstruction to the portal vein by cirrhosis of the liver tends to cause accumulation of fluid in the abdominal cavity.

It has been mentioned how great an influence dilatation of the arteries from vaso-motor paralysis has upon the *production* of œdema in cases where the veins are obstructed. Arterial dilatation may also produce a local œdema, even when no such obstruction is present, as, for instance, in the tissues around an inflamed part. It has been shown, however, by Winniwarter, that the walls of vessels in an inflamed part are more permeable, and allow fluids to pass through them more easily than healthy vessels will do. It is probably in consequence of this that we find that a slight stimulus, such as scratching the skin, which ordinarily produces in a healthy person only slight dilatation of the capillaries, and consequently redness of the part scratched, will produce an effusion from the vessels, and local swelling of the part at the point scratched, in persons suffering from urticaria. The same thing takes place when the skin is scratched in the neighbourhood of a part stung by a wasp.

But this alteration in the vessels is not the only cause of the œdema, which may occur without any obstruction to the circulation. An alteration in the composition of the blood appears to allow it to permeate more easily

into the tissues, and to produce œdema, even when there is no obstruction of the veins. In cases of anæmia we find œdema, occurring at the ankles, although there is no obstruction to the venous circulation other than that caused by the weight of the column of blood itself. In these cases, however, we have dilatation of the vessels, as is shown by the form of the sphygmographic tracing, and an altered composition of the blood is evidenced by the anæmic look of the patient. In albuminuria the altered composition of the blood appears to be the chief factor in the production of œdema, as the pulse in such cases may be hard, evidencing arterial contraction, and not relaxation.

**ETIOLOGY.**—General dropsy affecting the subcutaneous tissue, the peritoneal cavity, and the internal serous cavities and organs generally, is usually the result of albuminuria, and most frequently of that form which depends on acute nephritis, or on fatty degeneration of the kidney. In cirrhotic disease of the kidney the loss of albumen in the urine is much less, and the alteration in the composition of the blood consequently is not so great as in the first-mentioned form. The arterial tension also is greater than usual, instead of being less. In the amyloid form the œdema is generally moderate.

The next most common cause of dropsy is tricuspid regurgitation, obstructing the venous circulation throughout the body. This regurgitation generally depends on dilatation of the right ventricle consequent upon obstruction to the flow of blood through the lungs, either from chronic bronchitis and emphysema, or mitral obstruction and regurgitation. Dropsy from cardiac disease generally appears first in the feet if the patient has been for some time in an upright position, while dropsy with albuminuria is often first remarked by a puffiness of the eyelids. In the former it appears where the greatest obstruction to re-absorption takes place, and in the latter case in those parts where looseness of the cellular tissue most readily allows of exudation.

Local dropsies have, as a rule, local causes. Even the swelling of the feet in anæmic young women, although dependent on a general cause, namely, dilatation of the vessels, and altered composition of the blood, is determined locally by the greater obstruction to the venous circulation which the pressure of the long column of blood in the veins between the feet and the heart presents. In general dropsy also, those parts which are most dependent are apt to become most swollen. It is not, however, always so, as in certain cases the dependent parts have been noticed to be less dropsical than the others. This curious phenomenon seems to be due to some vaso-motor nervous influence on the vessels of the dependent part. The local œdema of a brawny character, often noticed

around inflamed parts, is partially due to swelling of the tissues themselves, and partially to effusion of fluid between them. This effusion, as has already been mentioned, appears to be caused both by the dilatation of the vessels observed in inflamed parts, and by the greater readiness with which fluids pass through them.

**Dropsy in Serous Cavities.**—The serous cavities of the body—the arachnoid, pleura, pericardium, peritoneum, &c.—are now known to be large lymph-sacs, in communication with the general lymphatic system of the body. The fluid which exudes into them from the blood-vessels is, in the peritoneum and pleura, removed, at least in part, by a pumping action in the movements of respiration. The central tendon of the diaphragm contains spaces, the walls of which are alternately drawn apart and pushed together during its ascent and descent. Their separation draws up lymph from the abdominal cavity, and their compression forces it onwards through the lymphatic vessels. The same thing occurs in the costal pleura, during the respiratory expansion and contraction of the chest. The accumulation of fluid in serous cavities may be due, like its accumulation in the cellular tissues, either to diminished absorption or increased exudation. The diminished absorption occurs here in consequence of pressure upon veins, and possibly also from interference with the pumping action just described. Accumulation of fluid in the ventricles of the brain, or in the sub-arachnoid cavity, is chiefly due to compression of the veins of Galen. In the peritoneum it may be due to obstruction of the portal vein by cirrhosis of the liver or by the pressure of tumours; and it may occur to a greater or less extent in all cavities of the body from general obstruction of the venous circulation, by disease of the heart or lungs, in the same way as anasarca. It may also occur in these cavities from alteration in the blood, as in Bright's disease. Active dropsy may occur in a serous cavity from inflammation, and here the exudation of fluid is much more rapid than in passive dropsy, the vessels of the inflamed part being dilated and more pervious than usual.

**TREATMENT.**—The first thing to be considered in the treatment of dropsy is the removal of its cause, if this be at all possible. Where it is due to obstruction of a vein we must hinder, as much as possible, the accumulation of fluid in the vein, by preventing the part from remaining in a dependent position, while at the same time we try to aid the absorption of fluid by the lymphatics by gentle upward friction. Where it is due to obstruction of the circulation in the lungs, we must diminish, as far as possible, all obstruction to the pulmonary circulation by inhalations, emetics, and expectorants, pushed if necessary so far as to cause nausea or even vomiting.

Where the obstruction is due to dilatation or valvular disease of the heart, we must lessen the work the heart has to do, and insist in bad cases on absolute rest in bed or on a couch, in which the patient's position can be altered, but which he should not leave. An absolute milk diet, like that used in typhoid fever, is often of the greatest possible service, if it can be borne. At the same time we should aid the heart to contract more powerfully by the use of cardiac stimulants, such as alcohol and digitalis. Digitalis probably has a threefold action in cardiac dropsy, by strengthening the heart, by contracting the vessels, and by stimulating the kidneys. It strengthens at the same time that it slows the cardiac pulsations, and by making the heart contract more powerfully it keeps up the onward current of the blood more efficiently, and at the same time lessens the dilatation which tends to render the valves incompetent. Besides its effect on the heart, digitalis has also an action on the vessels, causing the arterioles to contract, and probably reducing the dropsy in this way. For the contraction of the arterioles produced by digitalis is exactly the converse of the condition which occurs after division of the vaso-motor nerves, and which, as we have seen, produces dropsy whenever any obstruction of the circulation exists. It is not known at present whether digitalis also causes increased absorption, but it seems highly probable that it does so, because we know that it stimulates the vaso-motor centre, and stimulation of this part of the nervous system has been shown by Goltz to increase greatly the rapidity of absorption from the lymph-sac of the frog. In addition to this action on the heart and vessels generally, digitalis possesses a specific action upon the vessels of the kidney. It is a powerful diuretic, and by thus lessening the amount of water in the blood it will tend to increase the absorption of serous fluid either from the cellular tissue or serous cavities. When digitalis alone does not succeed, the addition of squill and of a small quantity of blue pill frequently increases its efficacy. Digitalis succeeds best in dropsy caused by valvular disease or dilatation of the heart. Sometimes strophanthus, convallaria, or adonis vernalis may succeed when digitalis fails; but in general digitalis is best. It is not so useful in dropsy arising from renal disease, and here other diuretics are preferable. One of the best is spirit of juniper, given either as a mixture or in the form of Hollands gin. Spirit of nitrous ether, nitre, bitartrate of potassium, and broom are useful in all forms of dropsy. Caffeine is sometimes very useful. Theobromine, the active principle of cocoa, seems also to be useful, and a compound of it with salicylic acid and soda has been recommended under the name of 'diuretin.' Copaiba occasionally succeeds where other diuretics fail. It seems to be most successful in dropsy due to

cirrhosis of the liver. Hydragogue cathartics, such as compound jalap powder, elaterin, &c., which cause copious watery secretion from the intestines, supplement the action of diuretics, and relieve or remove dropsy by removing water from the body, as well as altering its nutrition. Calomel seems to have an almost specific diuretic action, and is useful either alone or in combination with other diuretics or purgatives. In some cases of Bright's disease considerable relief has been obtained by the profuse sweating induced by vapour baths, hot-air baths, jaborandi, or pilocarpine. When the dropsy does not yield to other remedies, the fluid must be removed by paracentesis in the case of serous cavities, and by small superficial incisions or punctures, or by the insertion of very fine trocars with drainage-tubes attached, in the case of the limbs.

T. LAUDER BRUNTON.

**DROWNING, Death by.**—The term 'drowning' is employed, in an extended sense, to signify death from submersion in a liquid medium, and in a more restricted sense to signify death in consequence of obstruction of respiration so caused. Now, though death must necessarily ensue from asphyxia, when the air-passages are submerged, apart from any other complication, asphyxia is not always the mode of death in those who were alive at the moment of submersion. For death may result from mechanical injuries, concussion, shock, syncope, or apoplexy in the very act, or at the moment, of falling into the water. Devergie estimates that 12·5 per cent. of deaths occur from one or other of these causes. In the remaining 87·5 per cent. the phenomena of asphyxia pure and simple are present only in 25 per cent., while in 62·5 per cent. these are more or less modified by the causes above-mentioned, to which must be added the benumbing influence of cold.

When death is not sudden from shock, &c., the ultimate result is the same in the swimmer or non-swimmer, if there be no escape or rescue. All efforts to keep above water fail, vain clutchings are made at whatever comes within reach, water is drawn into the lungs and more or less swallowed, all struggles finally cease, and the body sinks.

The indications of such instinctive efforts form the most important evidence of submersion during life. Drowning is not necessarily to be inferred in the case of a dead body removed from the water; for the body may have been thrown in after death from other causes—asphyxia among the rest.

**THE EVIDENCE OF DEATH FROM DROWNING.** This is cumulative, for we can scarcely say that there is any one indication invariably present which can be looked upon as due to drowning and to nothing else. But one or other, or more, of the following appearances are generally found.

*External.*—The face is either pale, or slightly livid, and frequently bloated if the body has lain some hours in the water. Water flows from the mouth when the body is turned face downwards. Foam at the mouth and nostrils is common; and the tongue is swollen and congested, closely applied to the teeth, or even clenched between them. The skin is pale, or marked here and there by livid discolorations, and the muscles of the hair-bulbs are rigidly contracted, causing the appearance of goose-skin, or *cutis anserina*.

The penis, according to Casper, is retracted, but the more common condition is one of semi-erection.

Indications of struggling are sometimes seen in excoriations of the hands, mud and sand under the nails, or even weeds, straws, or other small objects tightly clenched in the hands.

*Internal.*—The trachea, bronchi, and smaller air-tubes are congested and filled with a mucous froth, more or less tinged with blood. The lungs themselves are congested, œdematous, and pit on pressure. Pressure on them causes froth to exude into the smaller bronchial tubes, and on section a sanguinolent froth and water escape. Indications may be seen of sand, mud, or small weeds drawn deep into the air-passages along with the water in which submersion took place. Water is often found in the pleural cavity.

The stomach occasionally contains water. If this has any special character by which it can be identified with that in which submersion occurred, and not likely to have been drunk to quench thirst, it excludes the theory of its having been swallowed before submersion, and is a strong presumption, if it cannot be said to be a certainty, that it was swallowed during the death-agony, and did not find its way into the stomach after death. The same may be said of water in the lungs.

The right side of the heart and venous system in general frequently present the appearances characteristic of asphyxia; and the brain is often congested. See ASPHYXIA.

Without relying on any one sign as conclusive, we may say that a body which exhibits goose-skin, semi-erection of the penis, excoriations, &c., of the hands, froth at the mouth, water in the lungs and stomach, and congestion of the right heart and venous system, certainly died from drowning. In the presence of some and in the absence of other indications, a careful weighing of all the facts is necessary; but in most cases a satisfactory conclusion can be arrived at.

Complete submersion is usually sufficient to cause death within two minutes; but cases have been recorded of resuscitation after a much longer period. Many of these can be attributed to the exaggerated estimation of time by anxious on-lookers; but there are

other well-authenticated instances, which may be explained by the supervention of syncope and temporary cessation of the respiratory process. That which renders resuscitation after submersion less likely than after a corresponding period of mere suffocation is the entry of water into the lungs by aspiration.

**TREATMENT.**—The treatment of the drowned consists in the persistent use of artificial respiration (see **ARTIFICIAL RESPIRATION**; and **RESUSCITATION**) so long as any signs of life remain, together with the application of means to counteract the great abstraction of body-heat which occurs even when the aerial temperature is comparatively high. Before commencing the movements of artificial respiration, the mouth and nostrils should be freed from water and froth, by holding the head somewhat low, face downwards, for a few seconds. Artificial respiration should then be immediately proceeded with. At the same time the wet clothes should be removed, and the body wrapped up in warm clothes obtained from bystanders, pending the arrival of warm blankets, hot bottles or bricks, &c., from the nearest house. Assiduous friction of the extremities should also be kept up. These directions—artificial respiration excepted—naturally presuppose assistance. If this be not at hand, the operator must rely mainly on artificial respiration. In the performance of artificial respiration by Sylvester's method, especial care must be taken against pressing on the stomach, for as it so frequently contains water, this may be forced up the œsophagus, and drawn into the lungs by the next inspiratory movement.

When spontaneous respiratory movements commence, attention should be directed to maintain life by the application of warmth externally, assiduous friction of the limbs upwards, and the administration of brandy and water, wine, or coffee. Lung-complications should be watched for and counteracted.

D. FERRIER.

**DROWSINESS.**—Inclination to sleep. See **SLEEP**, Disorders of.

**DRUG-ERUPTIONS.**—**SYNON.**: *Dermatitis medicamentosa*.

Many medicines produce at times various eruptions or discolorations of the skin, owing to idiosyncrasy, irritability of the gastrointestinal mucous membrane, or defective power of elimination on the part of the patient; or, on the side of the drug, from the largeness of the dose or its long-continued administration.

These toxic lesions may be divided into three classes:—(1) Those inflammatory eruptions which are *special to the drug*, such as the agminated pustular eruptions produced by bromine or iodine compounds (see **BROMISM**; and **IODISM**). (2) Various inflammatory eruptions *not distinctive in*

themselves, their nature being only recognisable from the surrounding circumstances. (3) *Discolorations* of the skin, such as are produced by arsenic and nitrate of silver. See **PIGMENTARY DISEASES**.

The great bulk of medicinal eruptions are either erythematous or urticarial, but the kind of eruption produced by the same drug often varies according to the individual who takes it. With the exception of the special eruption of iodides and bromides, the lesions are probably due to irritation of the gastrointestinal mucous membrane acting reflexly on the vascular nerves of the skin; for in many instances the dose has been too small, and the eruption has followed too quickly on the ingestion of the drug, for the rash to be due to the absorption and circulation of the substance itself. With the exception of the special bromide and iodide eruptions, the diagnosis cannot be made from the aspect of the rash. The following lists do not pretend to be quite complete, but represent all the chief eruptions and the drugs which produce them:—

#### List of Drugs and of the Rashes which they Produce.

*Antipyrine (Phenazone).*—Erythema—diffuse, patchy, papular, or morbilliform; urticaria; miliaria.

*Arsenic.*—Erythema—diffuse and erysipelas-like, papular; acuminated or morbilliform; urticaria, vesicles, pustules, furuncles, herpes zoster, gangrene, pigmentation.

*Belladonna.*—Erythema—diffuse, scarlatiniform, or patchy.

*Benzoate of sodium.*—Erythema—patchy.

*Borax.*—Psoriasis, or a scaly eruption like it.

*Boric acid.*—Erythema, followed by vesicles.

*Bromine compounds.*—Erythema—diffuse, patchy, papular or morbilliform, 'nodosum'-like; urticaria, bullæ, pustules—discrete or agminated, furuncles, ecchyma (indirectly), eczema.

*Calomel injection.*—Erythema, scarlatiniform in one case.

*Cannabis indica.*—Vesicles.

*Chloralamide.*—Erythema.

*Chloral hydrate.*—Erythema—diffuse, papular, and scarlatiniform; urticaria, vesicles, bullæ, pustules, purpura, shedding of nails.

*Chlorate of potassium.*—Erythema, papular; discoloration, bluish or icteric.

*Chloroform.*—Purpura.

*Chrysarobin.*—Erythema—diffuse, with œdema, eczema, once pityriasis rubra.

*Cod-liver oil.*—Vesicular, pustular.

*Copaiba.*—Erythema—diffuse, patchy, or scarlatiniform; military papules, petechiæ, vesicles, bullæ, urticaria.

*Cubebs.*—Erythema—papular, military, or morbilliform.

*Digitalis.*—Erythema—scarlatiniform or papular.

*Iodine and its compounds.*—Erythema—diffuse, papular, morbilliform, or nodosum-like; urticaria, discrete pustules, vesicles, purpura, gangrene.

*Iodoform.*—Erythema—diffuse or scarlatiniform; papules, vesicles, bullæ, eczema, purpura.

*Mercury.*—Erythema—diffuse, like erysipelas.

*Morphine and opium.*—Erythema—scarlatiniform, papular, morbilliform; vesicles and bullæ; never any rash from hypodermic injection.

*Phosphorus.*—Bullæ, purpura, icterus.

*Quinine.*—Erythema—diffuse or patchy, scarlatiniform; papules, acuminate or morbilliform, urticaria, vesicles, bullæ, furuncles.

*Salicylic acid and its compounds.*—Erythema—diffuse; urticaria, vesicles, pustules, purpura.

*Salol.*—Urticaria.

*Santonin.*—Urticaria.

*Strychnine.*—Erythema—scarlatiniform.

*Tar.*—Erythema; locally a form of acne.

*Terebene.*—Erythema—papular.

*Turpentine.*—Erythema—diffuse, papular, acuminate, or morbilliform; vesicles.

#### List of Eruptions and of the Drugs which produce them.

*Diffuse or patchy erythema.*—Antipyrine, arsenic, belladonna, benzoate of sodium, boric acid, bromides, chloralamide, chloral hydrate, chrysarobin, copaiba, iodides, salicylic acid, stramonium, tar.

*Scarlatiniform erythema.*—Belladonna, chloral hydrate, copaiba, iodoform, quinine, strychnine, bromide of nickel.

*Papular or morbilliform erythema.*—Antipyrine, arsenic, bromides, chloral hydrate, cubebs, morphine, quinine, terebene, turpentine.

*Nodosum-like erythema.*—Bromides and iodides.

*Urticaria.*—Antipyrine, arsenic, bromides, copaiba, iodides, morphine, quinine, resin, salicylic acid, salol, santonin.

*Vesicles.*—Cannabis indica, chloral hydrate, cod-liver oil, copaiba, iodides, morphine, quinine, salicylic acid, and turpentine.

*Bullæ.*—Bromides, cannabis indica, chloral hydrate, copaiba, iodides, morphine, phosphoric acid, quinine.

*Pustules.*—Arsenic, bromides (confluent), chloral hydrate, iodides (isolated), salicylic acid.

*Purpura.*—Chloral hydrate, chloroform inhalation, iodides, quinine, salicylic acid.

*Pityriasis rubra (?)*.—Bichromate of potassium.

*Psoriasis (?)*.—Borax, bichromate of potassium.

*Eczema.*—Bicarbonate of potassium, bromides, chrysarobin, iodoform.

*Gangrene.*—Arsenic, ergot, iodides, quinine.

*Persistent desquamation.*—Quinine.

*Abscess.*—Quinine.

*Furuncles.*—Arsenic, bromides, quinine.

*Keratosis palmaris.*—Arsenic.

*Pigmentation.*—Arsenic, nitrate of silver, picric acid.

*Herpes Zoster.*—Arsenic.

H. RADCLIFFE CROCKER.

**DRY.**—SYNON.: Fr. *Sec*; Ger. *Trocken.*—A term applied to certain morbid conditions, to express the entire or comparative absence of fluid exudation or secretion, which is often present in such conditions; for example, Dry Gangrene, Dry Cavity, Dry Catarrh, and Dry Pleurisy. The word is also associated with certain auscultatory signs, which convey the impression of want of moisture; for example, Dry Rhonchus and Dry Crackle. See PHYSICAL EXAMINATION.

**DUCHENNE'S PARALYSIS.**—See PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS.

**DUCTUS ARTERIOSUS, Patency of.**—See HEART, Malformations of.

**DUMBNESS.**—DEFINITION.—The condition of an individual considered incapable of articulating sounds.

Dumbness may arise from a variety of causes, and its prognosis and treatment vary accordingly.

1. **Dumbness due to deafness.**—The most frequent cause of so-called dumbness is congenital or early acquired complete deafness, or defective power of hearing, so that the patient is unable to acquire in an ordinary way the knowledge of articulate sounds. It is important to bear in mind that complete deafness is not essential to this peculiarity. Dumbness is frequently met with in children and others where the only cause is *defective* power of hearing.

**TREATMENT.**—Whether the outcome of complete or partial deafness, the treatment must be based on the belief that the articulating power is latent, and may be developed by teaching the patient to imitate the process of speaking in others, and by a methodical training in lip-language. It is most important that sign-language should not be cultivated at the same time, and that if a language of signs, whether by the hand or gesture, has been previously taught, it should be thoroughly and at once discarded. With patients who have full intellectual power, and who are trained as indicated above, it will be found that for them dumbness is a misnomer, articulate sounds, although with a defective modulation, being readily acquired. Individuals coming under this category are erroneously called deaf-mutes.

2. **Dumbness from central lesion of the hypoglossal nerve.**—This may arise from cerebral hæmorrhage, tumours, or embolism, and the prognosis is most unfavour-

able. It is usually associated with other paralytic conditions, but is of all the most persistent.

**3. Dumbness from peripheral lesion of the hypoglossal nerve.**—This is much less frequent as a cause of dumbness than central lesions; nevertheless cases are met with where hydatid or other tumours result in dumbness through pressure on the nerve itself.

**4. Dumbness from lead-poisoning.**—Among the paralyzes arising from the slow effects of imbibition of lead is paralysis of the tongue, with consequent loss of articulating power. This defect is usually associated with grave impairment of other parts.

**TREATMENT.**—The treatment of dumbness due to lead-poisoning will be best effected by elimination of the poison by the administration of iodide of potassium, and the judicious employment of galvanism to the nervous system.

**5. Dumbness from congenital defects of the tongue or of the palate.**—Various congenital local lesions are met with giving rise to dumbness.

**TREATMENT.**—Many of these cases are remediable by surgical or surgico-dental help, followed by methodical teaching.

**6. Dumbness from emotional lesions.** Dumbness occasionally arises from great emotional disturbance, such as great anger or sudden fright. Moreover, it is often met with, without such marked cause, in individuals, especially of the female sex, having a highly developed emotional life.

**TREATMENT.**—Cases of this kind are usually successfully treated by faradisation about the muscles of the neck; the patient at the same time being encouraged to call his articulating power into action, and in proportion to his success the faradic current being discontinued. The moral treatment here indicated may be greatly assisted by promoting the general health, and placing the patient under the best possible circumstances as to hygiene and moral discipline.

**7. Dumbness from intellectual disorders.**—This is by far the most common cause of true dumbness. It may arise from idiocy or imbecility of a congenital nature; from that which has been acquired early in life; or from dementia as the outcome of acute or chronic brain-disease in middle or advanced life. Among the congenitally feeble-minded, dumbness is a very frequent phenomenon. This arises from the association therewith of deformed mouths and highly-arched palates; from defective power of co-ordination of the muscles of the tongue; and from an inability to transform ideas into word-signs. In the most profound cases there is such an absence of ideas that language of any kind is not required.

**TREATMENT.**—The treatment of this kind of dumbness is one which requires great tact,

and energy; and the success will be commensurate with these aids.

The physical health of the individual should be carefully attended to, so as to induce, by judicious food, frequent bathing, and warm temperature, the highest amount of nervous energy. The power of co-ordination should be sedulously cultivated by methodical exercises, especially of the hands, leading up to well-devised tongue-gymnastics. He should then be taught monosyllabic sounds, by being shown the object represented by the sound, while he imitates the sound when watching the teacher's lips. Having thus acquired the power of producing the word-sign by imitation purely, he is next taught to repeat it from memory when shown the object only. After nouns have thus been taught, the names of qualities and adverbial expressions should be added, and in this manner articulate speech built up.

Where the feeble-mindedness has been acquired after birth, the dumbness resulting therefrom should be treated in a somewhat similar manner to that having a congenital origin, but the prognosis is not so good.

Still more unfavourable is the forecast of dumbness when the result of dementia.

J. LANGDON DOWN.

**DUODENUM, Diseases of.**—These may be considered under the heads of—(1) *Functional disorder*; and (2) *Organic diseases*.

**1. Functional disorder.**—Disorder of the duodenum is said to produce a form of dyspepsia, characterised by pain in the epigastrium and right hypochondrium two or three hours after meals, vomiting, and the distant effects of ordinary dyspepsia—vertigo, headache, drowsiness, burning sensation in the soles of the feet and palms of the hands, &c. Imperfect chymification, which attends ordinary dyspepsia, may induce these symptoms by generating products which irritate the duodenum.

**TREATMENT.**—The treatment is mainly that of disordered digestion. The bowels and the diet are to be carefully regulated; and such remedies as alkalis, bismuth, oxide of manganese, prussic acid or hydrochloric acid exhibited, according to the special requirements of each case.

**2. Organic diseases.**—These are (a) *inflammation*; (b) *ulceration*; and (c) *new-growths*.

(a) **Inflammation.**—**SYNON.**: Duodenitis; **Fr.** *Duodénite*.—*Acute* inflammation of the duodenum is usually of a mild catarrhal character. It either forms part of an enteritis, or is an extension downwards of a similar affection of the stomach. The ordinary exciting causes are exposure to cold, and irritating ingesta or acrid bile. Usually the symptoms of slight gastric catarrh—a loaded tongue, anorexia, nausea, vomiting of tenacious mucus—are followed by jaundice. When the

duodenum is invaded there is said to be fulness and tenderness of the right hypochondrium. As a rule, however, new symptoms are not set up unless the bile-ducts become obstructed by mucus from extension of the catarrh into them, when jaundice supervenes without pain. The attack usually lasts a week or a fortnight, and, with suitable hygienic and dietetic treatment, it passes safely off. It is, however, sometimes followed by jaundice unusually prolonged, and, even when the bile-ducts are free, by prostration and wasting out of proportion to the mildness of the disease in itself. While catarrhal duodenitis does not afford characteristic symptoms, its presence is, however, usually suggested by painless jaundice following exposure to cold, catarrh of the stomach, and enteritis.

**TREATMENT.**—This consists in rest in bed, warmth, liquid diet, counter-irritation by blisters, mustard or hot poultices, and effervescent salines.

*Chronic inflammation*, resulting in thickening of the mucous and submucous tissue, and even adhesion of the duodenum to adjacent organs, is usually associated with chronic ulceration, or with cancer of the duodenum, pancreas, liver, or other structures. Contraction of the duodenum produces symptoms of obstruction similar to those arising from stricture of the pylorus.

(b) **Ulceration.**—*Perforating ulcer*, similar to that of the stomach, is said to be more frequent in men than in women (about 10 to 1), and rarely to occur during childhood; while it sometimes follows severe and extensive burns and scalds.<sup>1</sup> Fatal ulceration has not infrequently been reported in previously healthy subjects. It may then possibly arise from an accidental abrasion of the duodenal mucous membrane (by some indigestible substance), becoming subsequently subjected to the deleterious action of the gastric juice.<sup>2</sup> The ulcer, usually single and found in the upper horizontal portion, when recent has clean-cut edges free from swelling. The wall of the duodenum may be perforated, either without previous adhesion, being followed by

the signs of general peritonitis; or with adhesion to adjacent parts, such as the liver, the gall-bladder, the pancreas, the colon, the hepatic artery, or the posterior wall of the abdomen—into which ulceration extends to a variable extent. Cicatrization may take place with recovery, or it may induce stricture of the duodenum or obliteration of the bile-duct. As a rule the symptoms greatly resemble those of perforating ulcer of the stomach; more frequently, however, the disease is latent, and induces very obscure dyspeptic symptoms prior to fatal perforation. Jaundice is not more common than in the similar affection of the stomach. In burns and scalds perforation seldom occurs before the tenth day. The treatment should be the same as that laid down for gastric ulcer. See STOMACH, Diseases of.

The duodenum may be ulcerated by the action of a gall-stone passing into it directly from the gall-bladder.

(c) **New-Growths.**—The most important of these is scirrhus cancer, which may involve the walls of the duodenum, usually by extension. It tends to produce obstruction, or it may set up chronic duodenitis, or block up the bile-duct and thus give rise to jaundice.

GEORGE OLIVER.

**DURA MATER, Diseases of.**—See MENINGES, Diseases of.

**DURATION OF DISEASE.**—See DISEASE, Duration of.

**DYNAMOMETER** (*δύναμις*, power; and *μέτρον*, a measure).

**DESCRIPTION.**—The dynamometer is an instrument originally invented by M. Duchenne, of Boulogne, for measuring and accurately recording the strength of the hand-grasp, and also for measuring the traction power capable of being exerted by other groups of muscles. The result is shown by an index, which traverses a semicircular dial bearing a scale graduated so as to enable the observer to record the number of kilogrammes which the applied pressure or traction represents. In practice this instrument has been principally employed for estimating the absolute or comparative force of the hand-grasp; and, in view of this restriction, Duchenne's instrument is needlessly complex. It has, moreover, the absolute disadvantage of being a little too broad, and of requiring too much strength on the part of the patient to move the index over the lower figures of the dial. A patient with a small amount of motor power, especially if the hand is small, is often unable to set the index of this dynamometer in motion. A cheaper, simpler, and narrower instrument has therefore been devised by English makers, the index of which can be moved by the application of a much smaller amount of power. This consists of a simple elliptical ring of steel, to

<sup>1</sup> In explanation of the connexion between severe burns and duodenitis ending in perforative ulceration, Dr. William Hunter infers from his experiments with the subcutaneous injection of toluylendiamin (which he found to set up inflammation of the duodenum) that there may be derived from the burnt tissues and excreted through the bile irritant substances which excite ulcerative inflammation. Some recent observers (Fayrer, Bowly, and Perry), however, have failed to discover *post-mortem* evidence of the alleged causal relation between burns and duodenal ulceration; while others (Wilks and Macarthy) have shown the rarity of it. Doubtless the association is much less frequent than has hitherto been held; for example, Raymond Johnson found in the records of University College Hospital only two cases of ulceration out of ninety-three cases of burns (*Trans. Path. Soc. Lond.*, 1890).

<sup>2</sup> Myers, *Trans. Path. Soc. Lond.*, 1890.

the inner and anterior face of which is attached a brass semicircular dial graduated with two rows of figures representing pounds instead of kilogrammes. The compression of the steel ring, by lessening its shorter diameter, moves a metal bar projecting from and sliding in a groove behind the dial, and this by rack-work communicates its movement to the index.

USES.—The dynamometer is a useful instrument, inasmuch as it enables us accurately to ascertain the relative compressing powers of the two hands in cases of incipient or actually developed hemiplegia, and also to learn in a positive and definite manner, from time to time, the amount of improvement or the reverse which may have taken place. Since the power of the muscles of the forearm and hand, like that of other groups of muscles, varies a good deal with the general state of health of the patient, the dynamometer is also capable of yielding valuable information concerning the strength of the patient, even where we have to do with general debility from any cause rather than with a case of paralysis. Any instrument which, in the place of fleeting and more or less vague impressions made upon the mind of the practitioner at the time, enables him to make a more accurate record in figures in his note-book, is a clear gain to practical medicine—more especially when its use involves no appreciable loss of time.

H. CHARLTON BASTIAN.

**DYSÆSTHESIA** (*δυσ-*, with difficulty; and *αἰσθάνομαι*, I feel).—A term applied to impairment of any of the senses, but especially to that of touch. See SENSATION, Disorders of.

**DYSCRASIA** (*δυσ-*, with difficulty, or badly; and *κράσις*, a mixture).—A morbid condition of blood.

This term signifies more than a disposition to disease; it implies the presence of some general disease exerting its pernicious effects upon the blood. Hectic fever, septicæmia, and metastatic inflammations are diseased conditions referable to dyscrasia. A person sickening for a fever is the subject of a specific dyscrasia. See BLOOD-DISEASE.

R. DOUGLAS POWELL.

**DYSENTERY** (*δυσ-*, with difficulty; and *έντερον*, an intestine).—SYNON.: Fr. *Dysenterie*; Ger. *Dysenterie*.

DEFINITION.—A specific febrile disease, accompanied by considerable nervous prostration, and characterised by inflammation of the solitary and tubular glands of the large intestine; sometimes ending in resolution, but frequently terminating in ulceration, occasionally in more or less sloughing or gangrene; always, in the acute stage, accompanied by tormina and tenesmus, the latter being most marked when the disease is situ-

ated in the rectum or lower end of the sigmoid flexure; stools at first more or less fæculent, later on yielding dysenteric products without much if any fæculence, such as blood, mucus, slime, and gelatinoid exudation, or—as in the sloughing or gangrenous forms—like the washings of meat, and possessing a putrid or gangrenous odour, and so-called epithelial, ash-coloured, black, gangrenous, pus-infiltrated or tubular sloughs, chiefly consisting of tough, imperfectly organised exudation.

ÆTIOLOGY AND PATHOLOGY.—In almost all, if not in all, situations where malarious fevers abound, as in the vicinity of the swamps and sluggish rivers of tropical and sub-tropical countries, dysentery prevails in proportion to the intensity and frequency of these fevers. Where, on the other hand, intermittents and remittents have been extinguished by improved drainage and the conversion of marsh into cultivated land, it becomes equally unknown. In or near the tropics, Great Britain, Canada, the United States, and in many other parts of the world, its diminution has proceeded *pari passu* with the decrement of malarious fevers. There would, therefore, seem to be some intimate connexion between the causation of dysentery and intermittent and remittent fevers. Not that the immediate causes of malarial fevers and dysentery are identical: all that is meant is that under certain conditions they concur.

Paroxysmal fevers interfere materially with the nutrition and functions of the digestive organs, and with the proper nourishment and constitution of the blood. Violent congestion of the abdominal viscera is one of the special conditions of the different forms of ague. Both the liver and spleen are liable to temporary and repeated engorgement, and so in fact are all the organs which minister to gastric and intestinal digestion. Even where malarious poisoning may never have resulted in any of the various forms of periodic fever, it may impair the power of the organic nerve-centres and the muscular tone of the blood-vessels, thus disturbing the balance of the portal circulation, and leading to more or less permanent repletion or congestion. As the congestion is most embarrassing during digestion, interfering with the appetite, and the capacity for digesting and assimilating food, its repeated and prolonged existence must deteriorate the quality and modify the quantity of such important secretions as the gastric juice, the bile, the pancreatic juice, and those furnished by the follicles of Lieberkühn, and by Brunner's and the solitary glands. Crude alimentary principles are thus assimilated from the intestinal tract. The liver is especially liable to functional derangement from the stagnation and slowing of the portal circulation, and thus it happens that in dysentery hepatic impairment is almost an invariable accompaniment. Such being some of the abnormal conditions produced by the operation

of malaria in its active or latent form upon the chylipoietic viscera, it is not surprising that, under the prolonged strain, certain portions of the alimentary mucous membrane should break down. Why the solitary glands of the large intestine should be the special seat of dysentery, whilst the corresponding glands in the small intestine should, with few exceptions, escape, it is, in the present state of our knowledge, impossible to say. The most that can be hazarded is, that the elementary structures of these glands take on morbid action through the operation upon them of a *materies morbi* derived directly from their blood-supply. That this poison exists in the blood may be inferred from the fact that constitutional disturbance invariably precedes and accompanies the earlier stages of acute dysentery.

Unwholesome drinking-water is a fertile proximate and exciting cause of dysenteric disease. Bad and unwholesome food of whatever description, by providing aliment incapable of being perfectly digested, may act in producing the disease. In like manner impure air may, by preventing the proper aëration and depuration of the blood, and by promoting the retention in it of inassimilable material, light up dysenteric inflammation of the solitary glands. The transit of acrid and vitiated bile and other secretions poured into the digestive canal, often operates as an exciting cause, and frequently determines a morbid action which might be otherwise righted by resolution, to advance to ulceration, sloughing, or gangrene. It is thus that many a simple but neglected case, scarcely at first distinguishable from diarrhœa—unless indeed every evacuation is most carefully washed and scrutinised—ends in destruction of large masses of the mucous membrane, and death, from the conjoint effect of exhaustion and shock from the separation of the sloughs. Indigestible articles of diet, which cannot be reduced by the juices of the digestive tract to a condition admitting of ready absorption, may act as local irritants and exciting causes. Not only is this so in the earliest visible stage or that of active congestion, but it becomes much more susceptible of demonstration in the exudative and ulcerative phases of the disease, by the repeated investigation of the subjective and objective indications. Thus the aggravation of the tormina and tenesmus in adults and children is traceable to indigestion in diet, or to the passage of undigested morsels of food, recognisable in the stools. Sudden vicissitudes of temperature from a high to a low range, or exposure to damp and cold combined, especially when the vital powers are physiologically depressed, by checking the excretory action of the skin and diminishing the cutaneous circulation, augment the portal congestion and excite dysenteric disease. This is probably the reason why, in a

large proportion of cases, the onset of the disease is ushered in towards midnight or the early morning. The operation of epidemic influences in the causation of dysentery, signifies only that it is most prevalent at those seasons when malarious fevers are most abundant. As there is an intimate connexion between the existence of malaria and the prevalence of dysentery, it is not difficult to understand why, both as regards type and seasonal frequency, dysentery should bear a striking relation to the severity and seasonal prevalence of malarious fevers.

*Is dysentery a contagious or communicable disease?*—Whilst many of the older physicians held that dysentery might be spread by contagion from person to person, it may be affirmed that the experience of most modern practitioners is altogether opposed to this view. There is no clear and unimpeachable evidence to demonstrate that it is propagated in the same way as typhus or small-pox. Dysentery may possibly be communicable, like typhoid fever, through air, water, or food—liquid or solid—charged with material derived from the undisinfected and putrefying products of the disorder. Be this, however, as it may, the complete disinfection or destruction of the alvine evacuations should always be regarded as a sanitary measure of supreme importance.<sup>1</sup>

**ANATOMICAL CHARACTERS AND PATHOLOGY.**—The dysenteric process generally consists of a specific inflammation of the solitary glands (Parkes, Baly, and others). The *first* visible change is congestion, the vessels surrounding and penetrating the capsules being turgid and engorged with blood. The *second* change is augmentation of their contents from the accumulation of albuminous exudation, and enlargement 'from the size of a millet-seed

<sup>1</sup> It is more than probable that there are several varieties of dysentery, each of which is attributable to its own specific cause. Different micro-organisms have from time to time been described in this connexion; but, as there seems to be no consensus of opinion on the subject among observers, it is premature to conclude that dysentery is brought about by the direct action on the glands of the colon of any known micro-organism. The only parasite which has established anything like a claim to be considered specific to dysentery is the *Amœba coli*, discovered by Lösch in 1875. This amœba has of late years been frequently found in dysenteric discharges in places so widely separated as Russia, Central Europe, Egypt, the United States of America, and India. Moreover, it has been found, on more than one occasion, in the pus and walls of liver-abscess complicating dysentery. This association is not without significance; but, as the amœba is certainly not present in every case of dysentery or dysenteric abscess of the liver, we are as yet justified in regarding it mainly as an epiphenomenon grafted on certain cases of colitis and liver-abscess, and not as the specific cause of these diseases. The *Amœba coli*, which when alive displays the characteristic amœboid movements, varies in size from 0.02 to 0.035 mm., is coarsely granular, nucleated, and possesses one or more non-contractile vacuoles. See ENTOMOZOA.—EDITOR.

to a small shot' (Baly). The *third* change, provided the inflammation advances, is rupture of some of the capillaries in the interior of these little vascular glands, extravasation of blood, with the area of the ordinary dark point on the free aspect increased. The *fourth* stage is now marked by atrophy and molecular disintegration of the free aspect of the capsular wall, and escape of its morbid gelatinoid blood-tinged contents into the canal of the intestine. This is the rule; but, in very exceptional cases, the capsule may burst through the attached portion, lighting up inflammation in the neighbouring connective tissue and muscular coat. In a large number of instances the morbid process may stop short, under proper treatment, at any of the first three stages, and repair is then effected by resolution. In many cases the morbid action is cut short after the completion of the fourth stage, without further extension of the disease. The adjoining follicles of Lieberkühn do not, in these cases, necessarily participate, to any great extent, in the diseased process. Under these conditions, when the whole of the exudation has been expelled, the glands regain their tone and functions, and recovery—rapid and complete—ensues. It is not often possible to illustrate these conditions in the *post-mortem* room; because, when death supervenes from dysentery alone, the ravages committed upon every structure of the mucous membrane are so extensive as to destroy the earlier physical phases of the disease. In some cases, however, which have died from intercurrent affections, the writer has been able to demonstrate the earliest stages successfully to his students, at a period prior to the implication of Lieberkühn's follicles, of which the mucous membrane is in great part composed, and to exhibit to them the gelatinoid exudation, termed by others 'gelatinous mucus,' free from or tinged with blood taken from enlarged and diseased solitary glands (*Indian Annals of Medical Science*, p. 190, No. xxiii., 1868).

When, owing to neglect, to constitutional defect in spite of the most careful therapeutic and hygienic management, or to intensity or quantity of the specific poison, the disease is not cured by resolution, the disintegrating or ulcerative process is developed. The whole of the solitary glands engaged perish. The ulceration involves the neighbouring tubular glands, leading to ulcers varying from the size of a mustard-seed to that of a florin or more, in depth generally extending to the submucous connective tissue, and not infrequently laying bare the circular lamina of the muscular coat, sometimes involving the longitudinal layer and perforating it as well as the peritoneal coat, thus admitting of the extravasation of the contents of the bowel into the peritoneal cavity, and lighting up peritonitis, which, if general, is invariably

fatal, but which, if local and confined to the close vicinity of the perforating ulcer, is not necessarily so.

The ulcers vary in appearance, size, and shape. They may be mere abrasions without much loss of structure; *minute*, though penetrating rather deeply into the submucous connective tissue; *irregular*, *serpentine*, or *rodent*, with here and there portions of the surrounding mucous membrane undermined and patulous; *transverse*, embracing partially, or completely, the entire circular outline of the mucous membrane; *circular* or *oval*, with regular and even margins; or *tubercular*, involving the whole substance of the mucous membrane, looking as if they had been punched out of it. These ulcers, as generally observed in the *post-mortem* room, are free from sloughs, and present a pale ashy appearance. Sometimes they are of a vermilion or purple colour, from active or passive congestion. They are often covered with flakes of tenacious lymph or exudation, and this may sometimes be seen spread over the neighbouring mucous membrane. The floors of these ulcers are usually formed by inflamed and thickened submucous areolar tissue; but sometimes this has all been destroyed, and then they are constituted of the muscular coat, thickened and infiltrated by inflammatory products; and when the muscular structure has itself yielded to the ulcerative process, they are made up of congested and swollen peritoneum, which, as already stated, occasionally becomes perforated.

When the ulceration proceeds solely by molecular disintegration massive sloughs are not observed. But when, as not uncommonly happens in asthenic, malaria-stricken, tubercular and worn-out constitutions, tissue-death occurs *en masse*, at an early period of the attack, sloughing of the mucous membrane is to be seen, together with portions of the muscular coats, or gangrene. These sloughs, or gangrenous portions of tissue, may be limited in extent. Some or all of them may be successfully detached during life, and can be identified as they are examined from time to time in the stools. In the *post-mortem* room they may be found partly detached and lying loose, mixed with the fluid contents of the bowel, or attached more or less firmly; sometimes compact, nodular, echymosed, grey or olive-coloured, green or yellow and pus-infiltrated, black, flaky, shreddy, shaggy, flocculent like pieces of teased cotton-wool, or ragged and stringy. In the truly gangrenous dysentery, the mucous and muscular coats are enormously thickened, and large portions are found gangrenous, varying in colour from a pale olive to purple or black. These appearances and conditions may be restricted to the cæcum and ascending colon, or to the sigmoid flexure, but sometimes they are co-extensive with the internal structure of the large intestine from the ileo-colic valve to the anus.

When the ileo-colic valve becomes destroyed, invagination of the lower end of the ileum into the cæcum sometimes happens, causing intestinal obstruction. Occasionally many inches of the gangrenous mucous membrane, with or without the muscular coat, are found either hanging loose in the lower part of the gut, or in process of being detruded from the anus.

In ordinary acute dysentery, advancing to ulceration or sloughing, repair is doubtless accomplished, as a general rule, by granulation and cicatrization. This process can be readily observed in dysenteric lesions of the mucous membrane of the lower end of the rectum, and in healing of the surgical ulcer within the verge of the anus. The reason why repair is frequently accomplished so slowly is because, owing to the irritation caused by the exalted vermicular contraction of the gut and the passage of flatus, fæces, and other products, it is impossible to command the physiological rest necessary for speedy and substantial granulation and cicatrization. Unless the destruction of tissue is very great, the contraction due to cicatrization does not occasion much future inconvenience. But if it embraces a large portion or the whole circumference of the mucous membrane, the subsequent contraction may produce dangerous narrowing of the calibre of the gut, or stricture of the sigmoid flexure or rectum. The thickening and contraction, especially in the attenuated victims of chronic dysentery, can be identified by physical examination. These constrictions are frequently the mechanical cause of constipation and fecal accumulations.

There is no valid reason for believing that the lost tissue is ever actually reproduced in true dysenteric ulceration. When the ulcers have been small, the contraction following repair is sufficient to bring the follicles of Lieberkühn on all sides into close juxtaposition. And this it is which has given rise to the impression among some pathologists, that the lost tissues have been renewed by a process of development and growth. But whenever the ulcers have been too large to admit of obliteration, microscopical examination shows that they have been bridged over by cicatricial tissue, devoid of solitary and tubular glands, and sparingly supplied with blood-vessels and absorbents.

In addition to the above anatomical characters, the mesenteric glands are generally found to be enlarged; and as an accompaniment or sequel, organic disease of the liver, or abscess, is not infrequently discovered to complicate the disease.

**SYMPTOMS.**—Every attack of acute dysentery is preceded by disordered digestion and constitutional disturbance, indicated by loss or capriciousness of appetite and furred tongue, constipation alone or alternated with looseness, dryness of skin, occasional chilliness

and general malaise, with slight rise of the evening temperature. These signs may be viewed as contemporaneous with the progress of the morbid action going on in the solitary glands. As the disease advances, there is more marked chilliness, succeeded by distinct feverishness. If the bowels have been confined, they now act spontaneously—expelling, at one or more acts of defæcation, almost the whole of the contents of the large intestine. If they have been loose, with or without aperient medicines, the fæculence is not so great in quantity. But in either case, beyond a little mucus, there is not as yet any discoverable dysenteric product in the stools. Prior to this conservative evacuation of the bowels, the febrile excitement sometimes runs high; there is thirst, bad taste in the mouth, flatulency, a variable amount of nervous and muscular debility, griping, an accelerated and irritable pulse, restlessness, disturbed sleep or actual insomnia. During, and immediately after, each evacuation there is tenesmus or painful straining—most intense in those cases where the disease is situated in the descending colon, sigmoid flexure, and rectum. The stools are offensive, but there is nothing at this stage pathognomonic in their odour. If, as frequently happens in private practice, the patient comes under treatment at this period, a small dose of castor oil guarded by laudanum, or a full dose of ipecacuanha, with absolute rest in bed and bland liquid nourishment, is sufficient, in a certain proportion of cases, to put a stop to the morbid action, and to promote cure by resolution in from twenty-four to forty-eight hours.

When, however, the disease persists, the symptoms continue in an aggravated form. The tormina and tenesmus become intensified; the desire to go to stool is more frequent, and to remain on the stool or bed-pan more irresistible and enduring, especially if the disease be concentrated in the sigmoid flexure or rectum. In rectal dysentery, there is dysuria, frequent micturition, and sometimes retention, from spasm due to reflex action, necessitating catheterism. The consumption of solid food—even of the most digestible kind—provokes and aggravates the tormina. The griping and tenesmus are now so intensified in degree, and increased in frequency, that each recurrence of them produces much depression and exhaustion, and a pinched and anxious expression of the countenance, with augmented frequency and weakness of the pulse. There is abdominal tenderness. During the acme of the tormina, the patient experiences difficulty in localising this tenderness. He will then declare that he feels agonising pain over the greater part of the abdomen, with or without the application of pressure. But in the absence of the tormina, careful palpation will enable the practitioner to localise it in those portions of the intestine

above the rectum which are affected by dysenteric inflammation. At this stage the tumefaction of the walls of the gut is seldom great enough to be distinguished through the abdominal parietes. The scanty stools are now characteristic, consisting of mucoid exudation tinged with blood, or bloody mucus or slime from the inflamed tubular glands, with isolated portions of gelatinoid exudation, more or less coloured with blood from inflamed and ruptured solitary glands, and with little or no feculence. These conditions are contemporaneous with the rupture of the affected solitary glands and a highly inflamed state of the adjacent follicles of Lieberkühn, as well as of the subjacent and intervening connective tissue. The muscular tissue, though not yet necessarily inflamed, is nevertheless hyperæsthetic. It is this hyperæsthesia which has more to do with the production of the agonising tormina than the diseased glandular organs implanted in and forming a constituent portion of the mucous membrane. These are the symptoms presented in a goodly number of cases met with in private practice, and in a smaller proportion admitted into hospital. The disease is said to have lasted from two to six or eight days. In uncomplicated cases, occurring in tolerably good constitutions, they generally yield, without extension of the mischief, to rest, bland liquid food, and full doses of ipecacuanha.

In cases which have been neglected or aggravated by indiscretions in diet and drink, or by diathetic or other defect of constitution, the dysenteric process passes on to ulceration. If the patient have not been brought under proper therapeutic and hygienic management, the tormina, tenesmus, local tenderness, and hardening of the superimposed abdominal muscles are augmented. The calls to stool are more frequent and painful. The urine is scanty and high-coloured, and is surcharged with lithates and biliary pigment. The stools mainly consist of the foreign products already described, but in greater quantity; are now possessed of a peculiar sickly smell; and yield portions of exudation in masses of greater or smaller size, simulating sloughs, but which, on microscopical examination, are seldom found to afford positive evidence of dead tissue-elements.

Unless the disease bend to treatment, it may terminate in sloughing. This may be either restricted or extensive. Death of portions of the mucous membrane is always accompanied by vital depression or well-defined muscular and nervous prostration, cardiac enervation, and an accelerated and feeble pulse. In some cases tissue-death *en masse* happens at an earlier period, even before the rupture of the solitary glands; and the sloughs can be discovered in the stools on from the eighth to the thirteenth day. The acme of vital prostration is manifested during the detachment of the sloughs, when the exhaustion is often

much increased by hæmorrhage. Improvement in the strength, volume, and slowing of the pulse, and in the expression of the countenance, the comparative relief from tormina and tenesmus, cleaning of the tongue, and the substitution of feculence for dysenteric products in the stools, signify, in these cases, the probable cessation or turning-point of the disease. The converse implies that the sloughing is extending, and a succession of sloughs of various kinds, with or without muscular structure, continues to be passed, which, in the process of separation, is accompanied by much bleeding, especially in patients poisoned by malaria or afflicted with the scorbutic or hæmorrhagic diathesis. The abdominal tenderness and hardening of the parietal muscles are marked during the separation of the sloughs. The affected portions of the colon can be felt to be swollen, doughy, and 'puddingy' (Chevers). The skin, in unfavourable cases, becomes clammy, features and eyes shrunken, body emaciated, appetite in abeyance, thirst great and distressing, tongue dry and brown, pulse feeble and running; the stools extremely offensive, bloody, slimy or watery, with varieties of sloughs and exudation. The sensibility becomes so blunted that the stools are passed without much pain—often involuntarily; and the patient eventually dies from sheer exhaustion from the extension of the sloughing, or the end may be accelerated by perforation of the bowel in one or more places, leading to extravasation of some of the contents of the intestine into the peritoneum, and general peritonitis.

Sometimes, from the commencement of an attack, or during the course of acute dysentery, rapid sloughing forms the chief pathological condition, passing into gangrene of large patches of mucous membrane, attended by increasing prostration and soon merging into collapse. As this extends until, in many instances, it involves almost the whole of the mucous membrane, submucous tissue, and muscular structure, it is characterised by intensified collapse. The tormina and the tenesmus, at first excruciating, suddenly disappear, to the delusive relief of the sufferer. Until the gangrene has spread to a great extent, the stools contain a large quantity of slime, blood, peculiar-looking exudation, and much gelatinoid exudation; but as the living mucous membrane becomes diminished, these products also decrease, and, in their room, we notice a watery product of a dark purple or black colour, resembling the washings of meat, giving off an incomparably offensive and gangrenous odour. To the naked eye, and on washing, these stools seem to be absolutely devoid of feculence. They yield a granular sediment of a black colour—gangrenous *débris* blackened by the combination of sulphur with the iron of disorganised cruorin. The abdomen, at first doughy, becomes tympanitic and free from pain on pressure,

and the surface cold and clammy; the countenance resembles the haggard and sunken appearance presented during the algid stage of cholera; the tongue is dry, brown, and fissured; the pulse is thready and rapid; food and medicines are rejected; the dejecta are passed involuntarily; perception is blunted; delirium supervenes; and the patient at last succumbs, worn out and exhausted, on from the sixth to the thirteenth day, according to the range and severity of the disease, and the constitutional power which he possesses.

**Chronic Dysentery.**—This is sometimes the result of acute dysentery, in spite of the most appropriate management, in persons poisoned by malaria and weakened by fatty or waxy degeneration of the spleen or liver, or both, and in strumous or scorbutic constitutions. The dyscrasia may be so pronounced that the material exuded is incapable of healing up the ulcers by granulation and cicatrization. The ulcers are repeatedly disturbed by peristalsis and the passage of flatus, fæces, undigested morsels of solid food, and the acrid unutilised secretions of the liver, stomach, and pancreas. Thus they are liable to become irritable from renewed congestion and inflammation. The muscular coat participates in the excitement, and becomes infiltrated with exudation, which eventually becomes organised and leads to thickening. The floors and sides of the ulcers are constituted of unhealthy structure. The difficulty thus experienced in effecting repair is augmented. In other cases the intestine becomes atrophied, attenuated, and transparent. The stools are made up of serous exudation, slime, blood, and sometimes of puriform material, with fæculence generally unformed. Almost every stool will be found on washing to contain dysenteric products. Very frequently, especially in cases which have been carefully dieted for a time, neither blood nor mucus can be detected in the stools, which appear to be of a purely diarrhoeic nature. The appetite is uncertain; the tongue often clean, shining, and devoid of epithelium; the pulse weak and irritable; and the abdominal tenderness easily localised. Thickening can often be detected. Tormina are always present; and unless the disease be confined to the cæcum or ascending and transverse colon, there is tenesmus. Multiple abscesses of the liver frequently supervene and carry off the patient; or after months or years of suffering he may perish from inanition and exhaustion, or from intercurrent disease.

**COMPLICATIONS.**—Acute dysentery is frequently complicated by the various forms of malarious fever, typhoid fever, the tubercular or the hæmorrhagic diathesis, purpura, scurvy, hepatic and splenic enlargement, malarious cachexia, or abscess of the liver; and in children by dentition. In every case of dysentery the strictest attention should be paid to existing complications. In patients

inhabiting marshy districts, and those following a seafaring life, the gums should be carefully scrutinised, and the cutaneous surface examined, with a view to ascertain the freedom or otherwise from purpuric or scorbutic taint. The history of the patient should be gone into, in order to make out the probable diathetic proclivities—acquired or hereditary.

**SEQUELÆ.**—That abscess of the liver, single or multiple, frequently follows acute and chronic dysentery, is indisputable; but whether as a result of the general condition existing, or of local pyæmic poisoning or embolism originating in the veins within the area of the ulcers, is still an open question. Dysentery sometimes terminates in permanent thickening of the parietes of the gut with eventual contraction or stricture, causing constipation, fecal accumulation or obstruction. When the seat of stricture can be reached, as in the lower part of the rectum, much relief can be afforded by simple incision and subsequent dilatation by means of bougies. Fissure of the anus, or ulcer within the verge of the anus, is a common sequel. Once diagnosed by examination of the stools and by means of the speculum, it admits of speedy relief by incision and after-surgical management.

**DIAGNOSIS.**—Dysentery can be diagnosed from diarrhœa by the abdominal tenderness, tormina, tenesmus, and the existence of dysenteric products in the stools. Dr. Edward Goodeve, late Professor of Medicine in the Calcutta Medical College, was the first to carry out the practice of washing the stools in dysentery and diarrhœa. The stools are first examined as they lie in the stoolpan. Water is then added in considerable quantity. After a short interval, to allow the dysenteric products to sink to the bottom, the supernatant fluid is gradually poured off. The washing is repeated until the foreign products remain clean and destitute of much smell. When these products are putrescent, or perhaps in all cases, it is convenient to wash the stools with a solution of carbolic acid or other colourless disinfectant. Dysentery is diagnosed from *fissure or ulcer of the rectum* by the fluid or loose character of the stools, with dysenteric products, and by the absence of ulcer, as determined by examination by means of the anal speculum.

**PROGNOSIS.**—*Favourable.*—The following are to be regarded as favourable features in the prognosis of any given case: The ordinary uncomplicated form of acute dysentery; early subsidence of the constitutional disturbance; a steady, firm, and strong pulse, with diminishing frequency and increasing power; moderate abdominal tenderness; absence of tympanites; a placid and normal expression of countenance; absence of sloughs or putrescent matters in the stools; early subsidence of tormina and tenesmus, with the

appearance of *fæculence* and the contemporaneous decrease of dysenteric products; return of appetite and power of digesting and assimilating food; and the absence of inflammatory or suppurative mischief in the liver.

*Unfavourable.*—Unfavourable features, on the contrary, are—The persistence of an elevated temperature; quick pulse, with increasing feebleness; sudden freedom from tormina, tenesmus, and abdominal tenderness, with great vital depression or collapse; doughy thickening of the colon, with dulness on percussion where there should be resonance; sudden increase of abdominal tenderness, with hiccough, nausea, vomiting, and great nervous prostration, tympanites, and peritonitic pain with constant hardness and tension of the abdominal muscles; increase of putrescent and gangrenous products in the stools, like the washings of decomposing flesh; excessive hæmorrhage from the bowel; bleeding from chapped and fissured lips, gums, and mouth; harsh, dry, black or glazed tongue; delirium; picking at the bed-clothes; and scantiness or suppression of urine.

*TREATMENT.*—Should an aperient be required in the congestive, exudative, or ulcerative stages of acute dysentery, or in sudden relapses supervening upon chronic forms of the disease, the readiest, simplest, and most painless is a tepid water enema of from two to four pints. After the operation of the enema, or immediately the patient presents himself suffering from any of these dysenteric conditions, in those cases where no preliminary aperient is indicated, a turpentine epithem or mustard plaster should be applied to the epigastrium for twenty minutes. At the same time, from twenty grains to a drachm of ipecacuanha, suspended in two drachms of syrup of orange-peel and four drachms of water, or in half an ounce of infusion of chamomile, with ten grains of carbonate of sodium or bismuth, or simply made up into conveniently sized pills, should be administered. The recumbent posture, with the head lower than usual, should be enforced. Liquids should be resisted as much as possible for an hour or two. Food should not be given for at least three hours before, and six hours after, the administration of the drug. Movement of every kind must be avoided; and the saliva should not be swallowed, but wiped away with a cloth. Thirst may be quenched by sucking pieces of ice, or, when this cannot be procured, by cold water in teaspoonsful at a time. Nausea will probably occur; perhaps, in some cases, retching and vomiting. When vomiting does occur it seldom happens before the lapse of an hour after the exhibition of the drug, and the ejected matter usually consists of small quantities of gastric secretion. Should the ipecacuanha be rejected, the dose should be repeated

as soon as the stomach has been tranquillised. It will be found beneficial to time the large doses, so as to allow of one being given night and morning, as long as their use is considered necessary. The signal for the relinquishment of these doses is freedom from tormina and tenesmus, with the occurrence of refreshing sleep, *fæculent*, bilious, or ipecacuanha stools, and restoration of the primary processes of assimilation. If no great amount of disorganisation of the mucous membrane have taken place, these favourable changes are frequently noticed after the administration of the first or second dose; and even if undoubted ulceration have set in, they are generally discerned on the second or third day, or earlier. In either case the drug should be abandoned, as the disappearance of the tormina and tenesmus, and the absence of mucus, blood, and slime from the stools, indicate the cessation of dysenteric inflammation, and that the affected portions of the bowel have been placed in the most favourable condition to undergo cure by 'resolution,' if the case have not proceeded to ulceration, or by 'granulation and cicatrisation,' if ulceration or even sloughing have already taken place. Chalk-mixture with hyoscyamus and astringents is now quite sufficient to complete the cure. In some cases ferruginous and bitter tonics are demanded, to give tone to the digestive organs, and to improve the condition of the blood. Counter-irritation, by means of turpentine epithems and mustard plasters to the abdomen, or fomentations, is a valuable adjunct in the management of the disease.

The diet should consist of chicken-broth, beef-tea, essences of chicken, mutton, or beef; sago, arrowroot, or tapioca; and small quantities of good port wine or brandy. During the active period of the disease all food should be given in a liquid form. The disturbing effect of the ipecacuanha given as above directed is only temporary. Abundance of time is, therefore, available between the large doses for the digestion and assimilation of liquid food. At the outset of dysentery, and as long as the tongue is coated, food should be avoided as much as possible; and when taken it should consist of very weak chicken-tea or barley-water. As soon as the tongue is clean a purely milk diet is the best. As the stools become more *fæculent* and consistent, solid food in the shape of tender chicken, lamb, and mutton, with biscuit and bread, light sago, rice, or tapioca pudding should be allowed. Potatoes and other vegetables should be avoided until the tone of the digestive system has been fully re-established. When the dysentery is complicated with a purpuric or scorbutic condition of the blood, the administration of the juice of the grape, orange, pomegranate or lime, and bael sherbet, are essentially necessary as dietetic rather than therapeutic agents.

Opium by the mouth is seldom required. When swallowed it 'locks up' the secretions of the liver, pancreas, and alimentary mucous membrane, rather favouring than reducing the inflammation of the solitary and tubular glands. These bad effects counterbalance the benefits derived from the sleep, diminution of peristaltic action, and temporary decrease of tormina and tenesmus consequent on narcotism. This explains why the real character of the disease is often completely masked by opium, and why apparent amendment is taking place whilst destructive ulceration and sloughing of the mucous membrane is rapidly extending. As ipecacuanha speedily brings about all the good without any of the evil effects of opium, this narcotic is not only superfluous but injurious in any form, excepting as an enema or suppository to relieve tenesmus, particularly in sigmoidal or rectal dysentery. There is less objection to uniting the ipecacuanha with such remedies as are acknowledged to possess the power of lessening the irritability of the stomach, and of increasing its tolerance of the drug, without interfering with the functional activity of those organs whose secretions we are endeavouring to promote with a view to rectify the disturbed balance of the portal circulation. On the contrary, medicines of this order may be beneficially associated with ipecacuanha—such as carbonate of sodium, bismuth, chloroform, camphor, and hyoseyamus.

When dysentery occurs in pregnant women, large doses of ipecacuanha are not contra-indicated; because, if the disease be allowed to proceed (which is more likely to happen under the old than the ipecacuanha treatment) abortion or premature labour is almost certain to follow; and when such a complication supervenes, in the later months of gestation, the mortality almost surpasses that of any other disease. When the dysenteric inflammation is summarily put a stop to by the ipecacuanha, abortion or premature labour is prevented. Under the opiate method of management, premature labour is not averted, but, in the majority of cases, occurs at the acme of the disease, when the sloughs are being thrown off; and the patient succumbs to the conjoint shock to the system. In dysentery complicated with pregnancy opiate enemata to relieve irritation in the rectum are more essential and permissible than under other circumstances.

In the acute dysentery of children ipecacuanha is invaluable. For a child of six months a grain, and for a child of one year two grains, should be given, with an equal quantity of carbonate of sodium, night and morning, until the tormina, tenesmus, and slimy and bloody stools are replaced by relief from pain and by feculent evacuations. It will not often be necessary to continue the drug beyond two or three days at a time. But it should be remembered that the disease

adheres with greater tenacity to children than to adults; and although we observe that ipecacuanha has an immediately beneficial effect in diminishing the blood, mucus, slime, and frequent stools, still we find that dysenteric or slimy motions with undigested food continue to pass. In that case the ipecacuanha, combined with chalk, bismuth, carbonate of sodium, or aromatic powder, should be repeated, once or twice a day, for a certain period, till healthy evacuations are restored. The gums must be lanced when necessary; turpentine liniment or stupes may be applied to the abdomen; weak chicken-broth or arrowroot should be temporarily substituted for milk; and, above all, food must be given in small quantities at a time, and at regularly stated periods. From the age of one year the dose is regulated by adding one grain for each additional year of age up to eighteen, when the doses indicated for adults should be employed.

In cases where evident malarious taint pervades the system and complicates acute dysentery, sulphate of quinine is indispensably necessary. A scruple of the antiperiodic will be most speedily absorbed if dissolved in water acidulated with sulphuric acid, and the exhibition of this may precede by an hour the first dose of ipecacuanha. Ten-grain doses should be given midway between the large doses of ipecacuanha, or during abatement of febrile excitement, until the feverish symptoms have been subdued. Quinine here is quite as important as ipecacuanha, for, until it has successfully checked the disturbing influence which malarious poisoning exercises upon the capillaries of the portal and general circulatory systems, the good effects which ipecacuanha produces are only temporary and incomplete. The mildest febrile exacerbations of a miasmatic origin re-excite dysenteric action, and thus undo the good effected by the action of the ipecacuanha. Hence the urgent necessity for removing without delay every vestige of masked or active malarious fever complicating dysentery. No drug enables us to accomplish this object so safely and so quickly as the sulphate of quinine in large doses.

When ipecacuanha fails to preserve the life of the patient, its failure may be generally attributed to—(1) coexistence of abscess of the liver; (2) unchecked malarious poisoning; (3) permanent enlargement of spleen or liver, or both; (4) irretrievable constitutional cachexia; (5) Addison's disease of the suprarenal capsules; (6) morbus Brightii; (7) phthisis or tuberculosis; (8) strumous disease of the mesenteric glands; (9) peritonitis, with or without perforation of the gut; or (10) the existence of extensive sloughing or gangrene.

The *advantages* of the 'ipecacuanha treatment' (for the revival of which the profession in India and England is indebted to Mr. Scott Docker, of the 2nd battalion of the 7th Royal Fusiliers, stationed at the

Mauritius.—*Lancet* of July 31 and August 14, 1858) in the congestive, exudative, and ulcerative stages of almost every form and type of acute dysentery, as well as in the acute attacks supervening upon chronic dysentery, may be briefly stated. They consist in (1) its simplicity, (2) its safety, (3) its certainty compared with any other method, (4) the promptitude with which the inflammation is stopped, (5) the rapidity with which repair takes place—(a) by resolution or (b) by granulation and cicatrisation, (6) conservation of the constitutional powers, (7) abbreviation of the period required for convalescence, (8) decrease in the frequency of chronic dysentery, (9) decrease in the frequency of abscess of the liver, (10) diminution of mortality to cases treated—all of which are accomplished, (a) without local or general blood-letting, (b) without salivation, (c) without calomel and irritating purgatives, and (d) without opium by the mouth.

Ipecacuanha in large doses may be said to fulfil many important indications. It produces: (1) all the benefits that have been ascribed to blood-letting without robbing the system of one drop of blood, (2) all the advantages of mercurial and other purgatives without their irritating action, (3) all the good results of antimonials and sudorifics without any of their uncertainty, (4) all the euthanasia ascribed to opium without masking, if not aggravating, the disease whilst the mischief is silently accumulating within. Thus, we possess in ipecacuanha a non-spoliative antiphlogistic, a certain cholagogue and unirritating purgative, a powerful sudorific, and a harmless sedative to the heart and the muscular fibres of the intestines.

The *objections* which have been urged against large doses of ipecacuanha in dysentery are, first, its 'depressing influence' kept up by nausea and vomiting; and, secondly, that it is liable to set up 'uncontrollable vomiting.'

First, the depressing power, nausea, and vomiting have all been over-estimated. Nausea is only a temporary and evanescent effect. Vomiting is an exceptional occurrence; and even when it does supervene, it seldom lasts long. As much nourishment, therefore, as may be required to support the strength can be given in the intervals between the large doses of ipecacuanha. But what contributes more to the conservation of the patient's stamina and to the prevention of depression or asthenia, is the speedy cessation of the dysenteric process accomplished by the drug, followed by refreshing sleep and the power of digesting and assimilating nourishing food. Such remarkable results as these soon reconcile any patient suffering from dysentery to an otherwise disagreeable remedy.

Secondly, when uncontrollable sickness and vomiting succeed the employment of this drug in the manner already recom-

mended, the existence of one or other of the serious conditions previously enumerated may be more than suspected. In the absence of these complications, unmanageable vomiting is seldom if ever witnessed. Hence, in a preponderating majority of the cases of dysentery met with this objection is quite untenable. The truth is that every physician who has used ipecacuanha in heroic doses soon learns that depression of the vital powers from it is not to be feared, and is surprised at the small amount of vomiting that follows its administration, and at the unexpected ease with which the stomach tolerates its presence.

When dysentery becomes *chronic* no time should be lost in counselling removal from a malarious to a non-malarious and mild climate. A sea voyage—provided easily digestible food can be secured—is often attended by the happiest results. To men so afflicted 'the salt ration,' as remarked by Dr. Maclean, 'is simply destruction.' The clothing should be warm, and flannels always worn round the abdomen; Dr. Maclean also recommends 'the use of a water belt over the abdomen for some hours daily. This acts as a fomentation, and the steady uniform pressure it maintains seems to favour the absorption of the fibrin effused between the intestinal coats. If there be much uneasiness about the fundament, a water compress over the anus affords more relief than opiate enemata.' The food should be chiefly concentrated soups, milk and lime-water, and sago, cornflour, arrowroot, &c., egg-flip with port, sherry, or brandy; or, if solid food can be digested, the tenderest chicken, lamb, or mutton, with bread and biscuit, may be allowed. Beyond airing in a carriage or chair, no exercise should be attempted. The position should generally be recumbent or semi-recumbent. The erect position excites peristaltic action, and thus disturbs the physiological rest required to facilitate the repair of the ulcers. Antiscorbutic juices should be given where there is the least taint of scurvy or purpura. Frequent blistering does much good; and all forms of counter-irritation are beneficial. In all obstinate cases a diet consisting of milk only ought to be tried; and also enemata of a solution of nitrate of silver ( $\frac{1}{2}$  grain to 1 fl. oz. of distilled water), two or three pints being passed up whilst the patient is in the knee-shoulder position and the pelvis well raised.

Gallic acid, acetate of lead, sulphate of copper, and nitrate of silver, are reputed to act beneficially. Dr. Maclean's favourite remedy, 'particularly in men returning from tropical regions, anæmic from loss of blood and the depraving influence of malaria, is the solution of the perntrate of iron. Under this remedy the whole system often rallies wonderfully, the condition of the blood improves, colour returns to the blanched cheek, the

stools become more natural and less frequent, the appetite improves, and digestion is more perfectly performed. The citrate of iron and quinine may after a time be substituted.' As nearly all chronic cases are underlain by a malarious taint, quinine should form an important element in the therapeutic management, and the greatest care should be taken to secure for the residence of the patient a climate at once mild and temperate and free from suspicion of malaria. Bathing during convalescence is an efficient and welcome auxiliary. Tepid or warm baths, medicated with Tidman's sea-salt or with nitro-muriatic acid, act in stimulating the secreting function of the skin. But it will often happen that, in spite of the most careful dietetic, hygienic, and therapeutic management, no substantial progress towards the repair of the ulcers is made, and the patient eventually dies, worn out from suffering and the asthenia consequent literally on inanition.

**EAR, Diseases of.**—SYNON.: Fr. *Maladies de l'Oreille*; Ger. *Ohrenkrankheiten*.

The natural division of the ear into external, middle, and internal, suggests a rational as well as a convenient classification of the disorders to which the auditory apparatus is liable.

**I. EXTERNAL EAR.**—In examination of the external meatus and tympanic membrane, bright diffused daylight, or, when this is not obtainable, light from a bull's-eye lamp lit with gas or electric light, is the best for illumination, and the light should be reflected from a concave perforated mirror of eight-inch focus down a tubular speculum. In any operative proceedings the mirror should be worn on the forehead, as in examining the throat, but otherwise should be held in the hand. As great variations in the calibre of the auditory meatus are met with, it is necessary to be provided with specula of several sizes, the most convenient form being that known as Gruber's.

Of the affections of the external ear the most important are the following:—

**1. Eczema.**—Although the acute form of eczema generally affects the auricle and external auditory meatus, it is far more common to meet with the chronic variety. Elderly females are especially subject to eczema of the ear, and it is to its long con-

tinuance that the remarkable narrowing of the external meatus throughout its whole extent, met with occasionally in the subjects of this complaint, is generally attributable. Such narrowing will often amount to almost complete closure, and it is in these instances that eczema becomes the cause of greatly impaired hearing; for when this condition is arrived at, the passage down to the tympanic membrane is at times so small as only to admit of a very small probe. It is for this reason that, although no special methods of treatment are called for, beyond what is necessary when parts other than the ear are affected with eczema, it is of the greatest importance to keep the meatus sedulously free from secretion, and this occasionally is not a very easy matter.

**2. Changes in cartilage.**—Another condition, in which the external passage becomes subject to partial closure, is shrinking of the cartilaginous part of the meatus. This, again, is a complaint of old age, and is attributable to no known cause. It is readily relieved by the patient wearing a piece of silver tube, to keep the passage patent.

**3. Bony Growths.**—Bony growths in the external auditory canal are of two kinds, true exostoses and hyperostoses.

(1) *True exostoses* arise from the junction of the osseous and cartilaginous portions of

the canal, owe their origin to acute inflammation, and are somewhat rapid in their growth. They present very little difficulty in their removal, inasmuch as they are attached by a pedicle, and are not composed of very dense tissue.

(2) *Hyperostoses* arise from the osseous part of the canal. These growths are of ivory hardness, and have a large base. They are occasionally single and confined to one ear, but generally are multiple, and more usually than not affect the meatus of both ears simultaneously. The form which they habitually assume is that of three growths, the apices of which meet, or nearly so, in the axis of the canal. Thus, seeing that a very small opening is quite enough to permit of the passage of sonorous vibrations to the tympanum, their presence remains undiscovered until a minute piece of cerumen completely closes an already nearly closed canal, and so by the deafness thus produced leads to their detection. Their growth is very slow, as they are observed to remain without increase for many years, and although without doubt they are at times congenital, it would seem that their existence is often called into being by a local irritation, first, because in a large number of cases the individuals so suffering have been for long periods addicted to diving; secondly, they are frequently preceded by a discharge passing for years through a perforated membrane and over the canal.

**TREATMENT.**—The occasions when these growths should be removed ought to be strictly limited to two conditions: 1st, when they interfere with the escape of purulent discharge, and so place the patient in danger of cerebral inflammation; 2nd, when by absolutely closing the canal they induce great deafness. In the large proportion of cases the occasional removal of cerumen which blocks up the small opening that remains is all that is necessary, and this should be done by the use of a small hook rather than by syringing, as the passage of water behind the growths is to be avoided. When, however, it is imperative to remove bony growths for either of the above-named reasons, the best method consists in drilling them away with a dental engine, to which may be attached drills of various shapes and sizes. This operation should be performed under reflected light, and ether must be given. Owing to the extreme hardness of the growths, this process occupies considerable time, but with due care it is not a dangerous proceeding. When the object in view is simply the relief of deafness, it is sufficient to drill away the apices of the growths, but when it is done for the purpose of providing a complete escape to purulent matter it is desirable to remove the chief part of the enlargement.

**4. Inflammation.**—The external auditory meatus is subject to inflammation, diffused or circumscribed, the latter occurring

in the form of small abscesses or boils. Both affections are attended by acute pain, and in each the general health of the patient has been out of order for some time previous to the local trouble.

**TREATMENT.**—Treatment in the direction of improving the general health, and local bleeding by means of leeches applied in front of the tragus, will often rapidly relieve the diffused form of inflammation; but when it has continued for a long period (as it not infrequently does), in addition to the soft tissues the periosteum becomes affected. The passage then throughout its whole extent becomes so swelled as to nearly close the external opening, and pain is constant. The only treatment which gives complete and permanent relief under these circumstances is to make two or three free incisions down to the bone, along the whole extent of the osseous part of the canal. A convenient instrument for this purpose is a small sharp-pointed curved bistoury. As to the propriety of opening abscesses in this situation there can be no question, for, owing to the extreme denseness of the tissues and their approximation to bone in the external auditory canal, abscess in this part is slow in its progress and attended with very great suffering. These abscesses being especially liable to recur, a proper regimen and medicines appropriate to the failure in general health are required.

**5. Fungi.**—The external auditory meatus has been occasionally found to be the seat of two varieties of vegetable fungus, namely, *Aspergillus flavus* and *nigricans*. The symptoms which they have given rise to have been great irritation and a slight discharge. They have been readily destroyed by syringing, and the local application of diluted spirit of wine or weak mercurial ointment.

**6. Polypus.**—Polypus of the ear is usually preceded by inflammation in the tympanic cavity and perforation of the membrane; it is considered along with diseases of the *middle ear*.

**7. Hæmatoma Auris.** See HÆMATOMA AURIS.

**II. MIDDLE EAR.**—All affections of the middle ear originate in some part of that tract of mucous membrane which, commencing where the Eustachian tube opens into the pharynx, forms the lining of this tube and of the cavity of the tympanum, finally becoming the innermost layer of the tympanic membrane. To the character of this tissue is due the term 'catarrh,' which, in its two forms of purulent and non-purulent, is used in describing any deviation from health which, directly or indirectly, is the cause of pathological change in the Eustachian tube or tympanum.

**1. Obstruction of the Eustachian Tube.**—One of the most frequent conditions under which the Eustachian tubes become

the seat of obstruction is that met with in children or young persons. The subjects of this affection present a very characteristic aspect. They breathe almost entirely through the mouth, which, sleeping or waking, is kept partially open; their tonsils are often enlarged, and they snore loudly during sleep. The mucous membrane of the nares and pharynx is swollen, and secretes in excess. Owing to this tumid state of the fauces the passages to the Eustachian tubes in this situation do not admit of the constant necessary supply of air to the tympana. The air in these cavities undergoes partial absorption, and thus becomes more rare than that external to the tympanic membrane; the density of the outer air remaining the same, the equilibrium from pressure is destroyed; the membrane, consequently, is retracted, the chain of ossicles is pressed inwards, and thus the conduction of sound becomes interfered with—in short, the patient is more or less deaf. In these cases inspection of the tympanic membrane at once reveals the state of affairs. As the cavity of the tympanum is not involved in the catarrhal change, its translucency and lustre are not impaired; the handle of the malleus is tilted inwards, the head of this bone is unusually prominent, and there is a distinct fold crossing the upper part of the posterior section of the membrane. Where the obstruction has lasted for a long period, the membrane will appear to be almost fallen in upon the walls of the tympanum, and the promontory and incus may be distinguished. If under these conditions the tympanum be inflated on Politzer's plan,<sup>1</sup> an instant return to good hearing follows, but in the course of a few days the improved hearing partially dies away, leaving the patient, however, in some degree better than before the operation.

In all these cases a thorough examination of the pharynx should be made, inasmuch as it will be frequently found that the symptoms above mentioned are due to masses of adenoid growths in the vault of the pharynx. This condition is especially indicated when, in addition to the apparent nasal obstruction, the intonation of the voice is of that peculiar kind as of a person speaking with a bad cold: thus—"diney-dine" instead of "ninety-nine." The only effectual way to explore the pharynx is to place the forefinger behind the soft palate as far up as the posterior nares. When adenoid vegetations are present, they can in this way be readily felt, and their size and position estimated. The posterior nares will often be found to be completely closed,

<sup>1</sup> This method of inflating the middle ear (now in such general use) consists in passing a stream of air from an india-rubber bag through one nostril whilst the patient swallows some water. The operator at the same time closes one nostril with the forefinger of the left hand, and completes the closure of the other with the thumb. The mouth must be kept firmly shut.

and in severe cases the pharynx throughout is absolutely filled with them. A rhinoscopic examination gives but a very inadequate idea of the condition.

**TREATMENT.**—When adenoid growths are present they should be removed, and if this is done thoroughly the patients recover their hearing completely in the course of a few weeks, and what is almost of equal importance (this applies to the general health), nasal respiration is quite restored. The best plan is without doubt to clear the pharynx at one sitting. This may be done either under ether, or without. In each case the patient's body should be well bent forward, in order that the blood should pass out through the nostrils. Unless this position is carefully attended to in the case of a patient under ether, there is great risk of blood dribbling into the larynx and being inhaled; for, these growths being very vascular, there is a good deal of bleeding. With this precaution, however, the pharynx can be cleared of adenoid growths by the nail of the forefinger in cases where they are very soft and friable; or in other cases (the larger proportion), when they are of firmer consistence, by the use of a steel nail (introduced to notice by the writer), adjusted to the forefinger. When it is found upon examination that adenoid growths are not present, the treatment of obstruction of the Eustachian tubes will be of a more simple character. It should include the gentle syringing of the inferior nares with warm alkaline solutions. The most useful of these contain bicarbonate of sodium and borax. In using them the head should be bent forward, and a small nasal syringe employed; this is preferable to the nasal douche, since the stream from the douche is so powerful as sometimes to rush into the Eustachian tubes, and so excite inflammation of the tympanum. Politzer's inflation should be employed, but not more frequently than two or three times in a week.

If the tonsils are so much enlarged as to interfere with the respiration, it will be necessary to remove them; but the reason for this proceeding is not that they press upon the openings of the Eustachian tubes, but because their presence keeps up the unhealthy condition of the pharynx.

Under this routine of treatment the patients completely recover their hearing; the space of time during which it is necessary to continue treatment varying according to the obstinacy which each case manifests.

Obstruction of the Eustachian tubes in *adults* presents certain well-marked differences from the affection as it prevails in *children*. An ordinary cold is the beginning of the trouble. It is more usual to find one instead of both tubes obstructed, and more often than not the tympanic cavity is involved in the catarrh. Where this is not the case—and it will be evident from the

retained lustre and transparency of the membrane—the same principles of treatment as are pursued in the case of children will hold good, except in so far that the affection in grown-up persons is less persistent after the tube has been once artificially opened; and that, to effect this, Politzer's method is sometimes not sufficient, or, even if so, not as efficacious as the Eustachian catheter. It must also be borne in mind that in the treatment of cases in which one ear is healthy, by means of the catheter the affected ear exclusively may be subjected to the air-douche, whilst with Politzer's method it is impossible to avoid forcing a stream of air into the healthy tympanum, and this is not always an advisable proceeding.

*The Eustachian Catheter.*—The following is the mode of using the Eustachian catheter: 'Place the patient in a chair, and let him lean back, and steady his head with the left hand firmly fixed on the top of it; hold the catheter lightly in the right hand, with the curve downwards, and pass it quickly in this position through the inferior meatus of the nose to the posterior wall of the pharynx. When this is felt, withdraw the catheter about half an inch, and tilt the point of the curved end rather upwards, and to the left or right, according to the side which is being operated upon. Now hold the catheter and end of the patient's nose steadily between the thumb and the first two fingers of the left hand. All this time the ear of the patient and that of the surgeon are connected with the otoscope. The point of the catheter is now supposed to be in the pharyngeal orifice of the Eustachian tube; but the only certain sign of this being the case is that when air is forced into the catheter it will be heard through the otoscope to impinge upon the tympanic membrane when a stream of air is passed down the catheter.'

The catheter may be made of silver or of vulcanite, but, of whatever material, it must be inflexible whilst being used. Beyond this, suffice it to say here that in practised hands its employment is invaluable, and indispensable in the treatment of most affections of the middle ear, not only in overcoming obstruction of the Eustachian tube, but also as a means by which injection of fluids may be applied to the cavity of the tympanum. In making use of the air-douche an india-rubber bag fitted to the catheter should be employed, and in using injections to the tympanum a similar arrangement is necessary.

**2. Catarrhal Inflammation of the Tympanum.**—When the tympanic cavity has become involved in the catarrhal state, or when the affection, instead of proceeding up the Eustachian tubes, begins in the tympanum, as it frequently does, those changes have commenced which, of all others, form the most frequent impediments to the conduction of sound—in other words, which make

the subjects in whom they are found more or less deaf; and it may be broadly stated that the extent to which this affection is remediable depends directly upon the time at which the patients suffering from it apply for treatment. In the early stages, the obstruction to the passage of sound through the tympanum is solely due to the effusion of mucus in this situation, and this is easily demonstrated by the moist gurgling sound which inflation of the tympanum produces, as may be heard upon connecting the ears of the patient and surgeon by means of a piece of india-rubber tubing.<sup>1</sup> Afterwards comes what may be termed the dry stage, *i.e.* when the fluid portion of the mucus has suffered absorption, and when any of the products of inflammation may have become more or less organised, or at least in a condition which, if not interfered with, suffers no further change. The morbid conditions which result from non-purulent catarrh of the tympanum are twofold. First, those which affect the tympanic membrane, and are, therefore, demonstrable during life; secondly, those which are met with after death in the tympanic cavity. The first of these include changes in curvature, in colour, and in consistence.

The slighter changes in curvature have been noticed in speaking of obstruction of the Eustachian tubes, which condition is necessarily more or less present in all cases where the tympanum has been the seat of catarrh, and these changes are met with indefinitely increased until the state of complete collapse is reached.

In this condition the membrane has the appearance of being in close apposition to the walls of the tympanum, and lapped round the ossicles, so that the forms of the malleus, incus, and sometimes the stapes are distinctly traceable.

In so extreme an example, the membrane is generally bound down to the tympanic wall by adhesions. The first change which the membrane exhibits is a loss of its lustre and transparency: it becomes opaque. Further alterations in colour, in cases of long standing, consist in the formation of patches of brown, yellow (colour of parchment), and white. Variations in consistency will include thickening throughout the membrane, or in parts of it, especially in the cases of dense chalk deposits (phosphate of lime); and thinning in places, so observable sometimes that inflation will induce bladder-like protrusions, which, as inflation is suspended, fall back again: changes in all these respects completely metamorphosing the appearance of the membrane. After death, within the

<sup>1</sup> This tubing should always be used, whether air or fluids are being injected through the Eustachian tube, for upon the sounds thus heard, as well as on the patient's own perception, depends the answer to the question whether the inflation is complete.

tympa-num may be found collections of dried mucus around the ossicles; thickening of the lining membrane; bands of adhesion in all directions; and ankylosis of the ossicles to each other, as well as between the stapes and fenestra ovalis.

As additional evidence during life of obstruction in the tympanum, it may be mentioned that sounds from a vibrating tuning-fork placed on the vertex are intensified when such obstruction exists, and the nerve remains unimpaired. This test is especially valuable where one ear is healthy, inasmuch as the sound will be heard exclusively on the deaf side, this being due to the fact that vibrations of sound thus conveyed to the auditory nerve, on their passage outwards through the tympanum, meet with the obstruction in this position, and are reflected on to the labyrinth. The appearances above described, together with the history of the case, serve sufficiently to distinguish affections of the conducting from those of the nervous apparatus; and the sounds which are produced upon inflation of the tympanum, whether of a moist or dry character, give evidence as to whether the mucus in the cavity of the tympanum is in a more or less fluid state, or has reached the dry stage where the fluid part of the secretion has become absorbed, the more solid portion remaining.

**TREATMENT.**—In the first of these conditions, the inflation at once increases the hearing power; in the second, it produces no change in the hearing. An indication in this direction is a most useful guide in respect of treatment, which may be said to include injections of fluid or vapours into the cavities of the tympana. In the matter of the selection of these remedies, the greatest diversity of practice exists in the hands of capable authorities. Astringent solutions of sulphate of zinc, alkaline injections of bicarbonate of sodium, iodide of potassium, chloride of ammonium, and the vapours of iodine, chloride of ammonium, each and all find favour. If fluids are injected, a few drops only are to be introduced through the Eustachian catheter, a small bulb of india-rubber being used to force the fluid through the catheter. Vapours are employed by means of the many apparatus in general use. The diversity of opinion on this subject shows how difficult a problem is the treatment of the ulterior effects of catarrh of the tympanum.

The degree of improvement varies within wide limits, but the greater benefits may always unhesitatingly be predicted during the moist stage of the catarrh. Indeed, the necessity for early treatment is abundantly shown, in the instance of catarrhal affection of the middle ear, by the extremely satisfactory termination of cases treated early in the disease, and the slight relief which but too often follows when the affection has been allowed to proceed for years unchecked. In

such cases as the latter, the fact that considerable quantities of inspissated mucus have been found in the tympanic cavities, first suggested the operation of making an incision into the tympanic membrane, and attempting the removal of mucus through the incision by passing a stream of air through the tympanum. This proceeding, with certain modifications afterwards introduced, is no doubt very useful in cases favourable for its employment, but it should be reserved for those which have defied the less severe means, and where there is unmistakable evidence of an obstruction to the passage of sound through the tympanum. Experiments with the tuning-fork, already referred to, give valuable evidence in this direction; but for a detailed account of this method of treatment, introduced some years ago by the late Mr. Hinton, the reader is referred to *Questions of Aural Surgery*. Suffice it to say here that an incision about one-eighth of an inch in length is made in the posterior section of the membrane with a cataract-needle, and through this opening an attempt is made to expel from the tympanum the morbid secretion. It is not within the compass of this article to refer to the many operations which have during the past fifteen years been suggested for the relief of tympanic affections, but as in most of these cases there is no doubt that the mucous membrane which lines the tympanic cavity is the primary seat of the disorder, not sufficient success has attended these efforts to stand the test of time, or probably some of them would be practised habitually by aural surgeons in this country, on the Continent, and in America. Such, however, is not the case. One of the causes of failure in all operative measures on the tympanic membrane is to be found in the fact that it is impossible to keep any opening in this structure from healing. That such attempts at relief should have been made is not surprising when it is remembered how intractable some of these cases are, how one of the forms of catarrh which affects the tympanum is slow and insidious in its progress, and sufficiently distinctive in its character, to have applied to it by general consent the term *proliferous progressive catarrh*.

**3. Purulent Catarrh of the Tympanum.—Perforation.**—The form of tympanitis in which the effused products become purulent, is an acute and generally an extremely painful affection. Usually the pus rapidly makes its escape from the tympanum into the external meatus, by a process of ulceration through the tympanic membrane, leaving as its result a perforation of this structure. In quite the early stage the affection may often be cut short by the free application of leeches in front of the tragus, followed by fomentations, but more often than not the membrane has given way before the patient comes under observation. Even then,

if the tympanic cavity be emptied of the pus by the free use of Politzer's inflation and repeated syringing, the opening will often close, and leave very little, indeed sometimes hardly any, appreciable deafness. If, however, a purulent discharge through the opening be allowed to go on unheeded for any length of time, it is the exception for the perforation to heal. This condition is constantly seen after scarlet fever, measles, or any of the exanthemata. A perforation of the tympanic membrane presents an infinite variety of aspects, from a small pinhole to nearly complete loss of the membrane, but there will always be a slight remaining external rim of membrane. This latter is perhaps the most frequent of all forms of perforation, and especially when the ulceration dates from an attack of scarlet fever. Although the handle of the malleus occasionally remains, it more usually comes away in these and other cases where the loss of tissue is very extensive. The head of this bone, however, may always be distinguished, unless there has been complete disorganisation of the tympanic cavity. Among other forms of perforation commonly met with may be mentioned those in which the anterior or posterior half of the membrane is left, and is bounded internally by the handle of the malleus; the so-called *reniform* perforation, where the lower part of the membrane is lost, and the umbo of the malleus indicates the position of the hilus of the kidney; and the small, smooth-edged circular perforation which is common alike to all parts of the membrane. Occasionally, though not very often, the tympanic membrane is the seat of a double perforation. Similar variations in hearing accompany this condition, between slight deafness and total loss of hearing power. The size of the perforation affords no guide in this respect, extreme loss of hearing being met with when the perforation is very small, and very slight deafness where the loss of tissue has been most extensive, so that it may be unhesitatingly stated that the loss of the membrane is but in a very small degree the cause of the deafness in these cases, the disorganisation in the tympanic cavity mainly accounting for this. Such disorganisation is at times so complete (especially after scarlet fever) as to include the loss of all the ossicles, total deafness, and paralysis of the muscles supplied by the portio dura. A very small perforation in the anterior and superior part of the membrane may from its position escape notice, but the diagnosis can be always verified by the facility with which air may be made to pass through the opening, or the reverse, provided that the communication between the Eustachian tube and the tympanum is not closed by cicatricial tissue—a very rare condition when so little of the membrane has suffered ulceration.

One other form of perforation deserves mention, rather on account of its frequency than its importance, namely, perforation of Shrapnell's membrane, which is that part of the membrane proper lying just above the short process of the malleus. Ulceration of this small area, which is merely a protective membrane, may exist without any impairment to hearing so long as the remainder of the tympanic membrane is entire, so that it would appear to perform no function so far as a conducting medium is concerned, but it is important to bear in mind that when it is perforated the lesion is at times connected with exposed bone.

**TREATMENT.**—The treatment of purulent tympanitis and perforation will include assiduous cleanliness; keeping the Eustachian tube free from obstruction; and the use of local remedies. Amongst the most useful of these are weak solutions of alcohol, and insufflation of gallic acid or boric acid. As the condition of the ear improves under these measures, so will the hearing power vastly increase when it has not been completely lost; but there still remains the oft-times invaluable application of what is spoken of as the *artificial* membrane. Of all kinds, the best undoubtedly is the flattened pad of moistened cotton-wool, applied by the patient, every morning, with a pair of forceps constructed for the purpose. Until this be tried in each case it is impossible to say whether it will do good; but when it is useful—as it is in a large number of cases—by its help the patient will recover very good hearing, and this even when the perforation has existed for a period of many years. That its effects depend upon the support which it gives to the ossicles, thus re-establishing the normal pressure of the stapes upon the fenestra ovalis, has been unquestionably demonstrated.

**4. Polypus.**—One of the most frequent complications in cases of perforation of the tympanic membrane is polypus, a term employed to designate a fleshy tumour in the ear. Although polypi are occasionally present in the meatus independently of perforation, the most usual situation from which they arise is the lining membrane of the tympanum. Sometimes the exact point of origin is the edge of a perforation, and still more rarely the sides of the meatus. In size these growths vary from a small protrusion through a perforation, to a tumour which entirely fills the meatus and projects externally from the ear. In this latter instance the growth presents a very distinctive appearance, not unlike a raspberry. Sections of aural polypi hardened in chromic acid with few exceptions show the structure to be fibro-cellular, the fibrous element preponderating over the cellular in proportion to the age of the tumour.

**TREATMENT.**—In all cases polypi should be removed, and the best instruments for this purpose are the rectangular ring polypus

forceps, or, in the case of a large growth, a Wilde's snare. Owing to their remarkable tendency to recur, removal is only the preliminary step in treatment. The principal part of this consists in their complete eradication by caustics. Of these the most efficacious and convenient is chloro-acetic acid, and later in the treatment nitrate of silver. The acid should be applied with great care by using it on the point of a probe defended by a small twist of cotton, and a convenient form of nitrate of silver is a bulb of the melted salt fused on to a probe or platinum wire. The caustic should be applied daily for some time after the polypus has been removed, and then less frequently. The treatment should also include the same scrupulous cleanliness and application of astringents, so desirable in the case of perforations. It is simply to the want of attention to details that failure in the treatment of aural polypus may be ascribed.

#### COMPLICATIONS OF TYMPANIC DISEASE.—

(a) *Facial Paralysis*.—This is due to inflammation around the portio dura in its passage through the aqueduct of Fallopius. When suppuration in the tympanic cavity, with caries of the bony canal, precedes or accompanies the loss of function in the nerve, recovery is hopeless; but when the paralysis follows a subacute catarrh of the tympanum, not ending in a perforation, as is sometimes the case, the paralysis in time disappears no less certainly than when it is dependent upon an affection of the nerve at a point after its exit from the temporal bone.

(b) *Pyæmia; Cerebral Abscess; and Meningitis*.—When the mastoid cells become the seat of inflammation, the pain, tenderness, and pitting on pressure over the mastoid process, will at once suggest an early incision down to the bone, and it may be truly said that this is often delayed too long, and perhaps is never done too soon. Again, when the symptoms point definitely to pus within the mastoid cells, the bone should be pierced so as to make the external opening communicate freely with the cells. Relief given in this way will occasionally be the means of saving life, by preventing the absorption of poisoned material into the lateral sinus. Besides pyæmia thus induced, other fatal issues which suppuration in the middle ear frequently entails have their starting-point in the tympanic cavity, and in such instances cerebral abscess or meningitis may be the immediate cause of death. In the latter case a *post-mortem* examination reveals pus in the arachnoid cavity, or between the roof of the tympanum and the dura mater; in the former case, the seat of the abscess may be either in the cerebrum or cerebellum; this portion of the brain (the cerebellum) being more generally, though not always, the part affected when the mastoid cells are involved as well as the tympanum.

The experience of the past few years has amply demonstrated the success which has attended the operation of trephining in those cases where symptoms point to cerebral abscess rather than to general meningitis. The operation should be done under strictly antiseptic conditions; the point selected should be over the temporo-sphenoidal lobe; and when pus is found after an exploration through this opening the wound should be kept carefully drained.

Fatal terminations of this nature most frequently occur when cleanliness and local treatment of the ear have been neglected. Hence the necessity for such care.

But the fact that even under the most favourable conditions such events are possible, when there is a fistulous opening in the tympanic cavity, should induce caution with insurance offices in accepting the lives of persons with this lesion, at the ordinary premiums. Fatal cases of this kind might seem in practice to be almost divisible into two classes—namely, those in which cerebral symptoms come on soon after the establishment of the perforation; and others where there has been a purulent discharge from the ear (that is, from the tympanum) for many years before the advent of such symptoms. In this latter class must be included those cases in which the temporal bone has become the seat of caries; and it may be stated, subject to no exceptions, that whenever exposed bone can be detected by means of examination with a probe within the cavity of the tympanum, the subjects of this condition are always more or less in a perilous state, and that at any time fatal symptoms may commence with a severe rigor, the earliest of all succeeding symptoms. For this reason, even when exposed bone cannot be absolutely demonstrated in the way mentioned, the existence of bone-granulations where there is a perforation of the tympanic membrane should be regarded as a most serious complication. The same danger, though in a very much less degree, may be said to be present when dead bone can be detected in the mastoid process—in a less degree, because the outer table of the bone is often affected whilst the inner remains healthy. The dead bone then in the former position becomes exfoliated, and the external wound heals. Such are briefly the points of importance in connexion with caries of the temporal bone. How caries of the mastoid process may be obviated by a timely perforation of the mastoid cells, and how the chief part of the temporal bone may when carious be removed and the patient survive, may be seen on reference to a paper entitled 'Disease of the Mastoid Bone,' by the writer of this article, in the *Transactions of the Medical and Chirurgical Society* for 1879.

(c) *Malignant Disease*.—In the paper just mentioned is also reported a case of malig-

nant disease of the ear, in which the cavity of the tympanum, having been the seat of suppuration for some time, became affected with epithelial growth, which caused the death of the patient. From all recorded cases of malignant disease of the ear, as well as those which have come under the writer's notice, it would seem that the seat of origin of the new-growth will be found to be the lining membrane of the tympanic cavity, and that a purulent discharge from this surface always precedes the appearance of the cancer, and must therefore be regarded as the exciting cause of the growth. In its early stages cancer in this situation bears a strong resemblance to the ordinary forms of polypus. The same cause, then, which in some cases calls into being a polypus, may occasionally give rise to malignant disease, and this without any predisposing cause (so far as can be ascertained) in the patient towards cancerous growth.

III. INTERNAL EAR.—Apart from deafness due to local changes in the external or middle ear, the function of hearing is subject to impairment from causes which have their seat in the nervous structures of the ear; in other words, although the conduction of sound may be good, the perception of sound may be faulty. The inability to hear the vibrations of sound conveyed through the cranial bones, such as from a vibrating tuning-fork placed upon the vertex, is indicative of this condition. For the rest, the absence of tympanic disease, and the history of the case, must supply the evidence required for a diagnosis. Familiar examples of this nature are the deafness which often accompanies old age, or which is left after fevers when the middle ear has not suffered; the two forms of syphilitic nervous affection to be presently mentioned; the sudden and sometimes total loss of hearing which occasionally follows severe mental shock; the deafness after loud explosions near the ear, so common in artillerymen and naval men; and that which is caused by blows on the head and boxes on the ear. An attack of mumps will sometimes leave behind an irremediable loss of hearing in one or both ears, unattended with any discoverable change in the tympanum. In a similar way weakly women occasionally become more or less deaf during their confinement, and this symptom becomes aggravated as each successive child is born. In connexion with this subject, prolonged suckling may be mentioned as one of the numerous debilitating causes which undoubtedly aggravate the trouble of an already impaired ear.

Among the nervous affections of the auditory apparatus possessing certain characteristics which serve to distinguish it from others is the so-termed Menière's disease, an attack of which at times gives rise to symptoms which would be alarming if their true origin passed unrecognised. A patient who suffers

in this way is seized with an attack of vertigo so severe that he not infrequently falls, and for some hours afterwards requires assistance in walking; occasionally vomiting succeeds the giddiness; and he recovers to find himself very deaf in one ear, with which previously he had heard well. Milder attacks of the same nature generally follow the first, and each one leaves the patient more deaf. Although with many writers it is a favourite theory that the seat of morbid changes in this disease is in the semicircular canals, up to the present the point has not been satisfactorily determined. No treatment appears to exercise any influence upon the disease. *See VERTIGO.*

**Syphilis.**—The affections of the ear due to syphilitic disease demand separate consideration. They occur under the following varieties: Firstly, in the form of sores and warts in the external meatus, which yield to local treatment. Secondly, affections of the middle ear during the secondary ulceration of the throat, the treatment for which, beyond specific medicines, in no way differs from what is useful in the ordinary catarrh of the same parts. Thirdly, failure in hearing power during the secondary stages, unattended with any change in the middle ear. This disappears under constitutional remedies. Fourthly, the loss of function in the auditory nerve, so commonly met with in the subjects of inherited syphilis. In these patients the hearing power begins to fail between five and fifteen years of age (very seldom later in life), and proceeds to very great and often total deafness, the period between good hearing and the extreme point of deafness arrived at varying from a few weeks to several years. From this cause children sometimes become in the course of a month or six weeks totally deaf, but such rapidity is exceptional. Experience has shown how powerless treatment is to arrest the progress of this affection, so that attention should be confined to preventing its subjects from becoming dumb, if they are attacked after they have acquired speech, and before they are likely to forget it, namely, from about four to seven years of age. This is best attained by teaching them lip-reading; and if they can read, by making them do so (*aloud*) several times each day. In this way a child will retain its recollection of language when otherwise speech would pass away. W. B. DALBY.

**EAUX-BONNES, in France.**—Sulphur waters. *See MINERAL WATERS.*

**EAUX-CHAUDES, in France.**—Sulphur waters. *See MINERAL WATERS.*

**EBURNATION** (*ebur*, ivory).—A state of bone-tissue in which it assumes the whiteness, smoothness, and hardness of ivory, in consequence of an increased deposit of calcareous matter. It occurs chiefly in rheumatic arthritis. *See RHEUMATIC ARTHRITIS.*

**ECBOLICS** (ἐκβολή, abortion).—This name is given to the measures which produce abortion, or expulsion of the contents of the uterus. In moderate doses ecbolic drugs may act as emmenagogues. See EMMENAGOGUES.

**ECCHYMOISIS** (ἐκ, out of; and χυμός, juice).—An extravasation of blood into the cellular tissue, due either to injury or to disease. It presents at first a more or less blue or bluish-black appearance, which changes with age, passing through green to yellow. See EXTRAVASATION.

**ECHINOCOCCUS** (ἐχίνος, a hedgehog; and κόκκος, a grain or berry).—See ENTOZOA.

**ECLAMPSIA** (ἐκλάμπω, I flash, I explode).—This term is now used as a synonym for convulsions, whatever may be their cause. See CONVULSIONS.

**ECPHYMA** (ἐκ, out of; and φῦμα, a swelling).—A growth from the integument. The term was employed by Mason Good as a designation for warts and corns, but is at present almost obsolete.

**ECSTASY** (ἐξίστημι, I amaze).—DEFINITION.—The term 'ecstasy' has been applied to certain morbid states of the nervous system, in which the attention is occupied exclusively by one idea, and the cerebral control is in part withdrawn from the lower centres and those for certain reflex functions. These latter centres may be in a condition of inertia, or of insubordinate activity, presenting various disordered phenomena, for the most part motor.

DESCRIPTION.—The subjects of ecstatic phenomena are commonly of the female sex, or are men who lead celibate and ascetic lives. To such individuals, they are in the present day almost confined. In the middle ages, on several occasions, under special circumstances, an intense dominant emotion, with some attendant ecstatic manifestations, was known to spread widely by a sort of moral contagion.

Women who are the subjects of this morbid state are usually single, frequently present menstrual irregularities, and often distinct evidences of hysteria, of which the ecstatic condition may be but a part. The immediate cause of the attack is usually some repeated vivid emotion, commonly religious, sometimes one of fear. The direction taken by the motor or other phenomena of the ecstatic state is often very obviously determined by imitation. With this direction there is associated, in some cases, the assertion of supposed facts, which transcend the ordinary course of natural phenomena, and which have been proved, in many instances, to depend on intentional fraud.

As forms of ecstasy we have the condition of some religious enthusiasts, in whose domi-

nant state all other mental processes are merged. Dreams and visions are determined by the ecstatic emotion and add to its intensity. Consciousness of the body may even be lost, so that all sensation is gone for a time; while the corporeal functions, including ingestion and egestion, are reduced to a minimum, and a little exaggeration may represent them as in complete abeyance. Hence the 'fasting girls' that have arisen in various countries, by whom 'stigmata' marks, in the positions of the nails employed in crucifixion, are sometimes presented, probably by artificial production, but possibly by the influence of the mental state on the processes of nutrition in the parts to which attention is directed. In some hysterico-epileptics a state of ecstasy—of rapt, intense emotion—forms part of the paroxysmal seizures, and then wild muscular spasms replace the tranquil repose of the more volitional ecstatics. Occasionally—when an intense emotion is shared by many persons—insubordinate muscular movements occur, of a rhythmical character, seen in the Jumpers and Shakers of the present day, and more strikingly in some of the dancing religious ceremonies of half-civilised races, and in the dancing epidemics of the middle ages. Such was the original dance of St. Vitus, in which the exciting emotion was religious; and such also the 'tarantella,' in which the excitant was terror at the supposed consequences of the bite of the tarantula, which the dance was intended to avert. The phenomena now manifested in the epidemics that have been described under the name of the 'Jumpers,' &c., merit, indeed, more detailed notice, since they have been observed in remarkable degree and conspicuous form in certain races in whom the process of brain development concerned in what we term 'civilisation' is taking place—with a slowness that is probably alike typical as regards the past, and instructive as to the process. The conditions especially favourable for the development of these disorders appear to be generated by the close contact of such races with those in whom the process of evolution of the nervous system has been carried farther; and the less developed organisation is, as it were, strained by a connexion which it is not strong enough to endure. At all periods a pathogenic influence has probably also been exerted by the excessive tension placed on some mental faculties by certain religious systems, but the effect is greater when the strain comes from without, and the nervous constitution is warped by the inequality between its own strength and that of the race with which it is not only in contact but attachment. The cerebral functions may be deformed by emotions that would be powerless to disturb a brain whose functions were strengthened by equal development in all parts.

It is especially among the negro tribes in contact with more civilised white races, that the most conspicuous forms of ecstatic disease have been observed. A condition described by Hammond under the term 'Miryachit' (Russian, *Miriatchit* = 'playing the fool') is almost identical with that met with in the so-called Jumpers. The subjects of this condition have been met with chiefly in Siberia; but an exactly similar condition is met with in Java, where it is known as 'Lata' or 'Latak.' Both sexes are liable, but most sufferers are females. It occurs in epidemics, especially involving several members of the same family; although sporadic cases are often met with. Contact with a person who is the subject of this affection is often the exciting cause; but sometimes the malady is distinctly hereditary. Natives and acclimatised immigrants are exclusively attacked, and of them only children and persons of a low intellectual development. The characteristic of the disease is that its subjects are compelled to imitate any sound, gesture, grimace, or act, even if it gives rise to pain, anger, or remonstrance. As a rule the malady is chronic, but presents spontaneous remissions. The general health is unaffected, and the patient is not incapacitated from work. Thus the chief difference between this condition and most other ecstatic states is, that the subjects of *Miryachit* re-act only and simply to impulses entering through the afferent optic and auditory channels; and when an order is given they do not perform the acts, but simply repeat the words of the order.

The state of 'sommolentia,' or 'sleep-drunkenness,' is closely allied, psychically, to the conditions under discussion, although differing in its associations, by which it is connected more closely with epileptic mania than with the ecstatic disorders. The subjects of this condition perform some act, it may be even of violence or murder, on being suddenly awakened from sleep—the action being often prompted by a dream.

The close resemblance between ecstasy and some forms of hysteria has already been alluded to; but what is of still greater interest is the fact that suggestion plays a most important part in all the conditions that have here been discussed, and that all these conditions seem, as it were, to form links in the chain which connects the dancing epidemics of the middle ages with the phenomena of suggestion and hypnotism of the present day.

A remarkable case is quoted by Hammond, of a gentleman who would perform any act he was told to by a person whispering into his ear while he was asleep.

**TREATMENT.**—It is rarely now that ecstatic manifestations have to be treated except as part of pronounced hysteria, and the treatment is that of the hysterical state which underlies the ecstasy. The measures of para-

mount importance are the substitution of a 'healthy moral atmosphere' for that under which the symptoms have arisen; and the exposure of actual fraud. Occasionally, even now, examples of solitary ecstasy come under observation. In these cases considerable care and tact are needed. Ecstasies are not amenable to the motives which influence most persons, and, if there is actual fraud, will sometimes die rather than be found out. In the case of fasting girls, due observation of the body-weight during a short time will answer as well as, and is much safer than, a long exclusion of food. But the removal of the ecstatic to other surroundings is the most important step for both detection and cure.

W. R. GOWERS. J. S. RISIEN RUSSELL.

**ECTHYMA** (ἐκθύω, I burst out).—A pustule or pimple; pathologically occupying a mid-place between a pustule and a furuncle. The so-called tar-acne, the small inflammatory pustules developed around a mother-boil, and the commoner eruptions produced by iodine and bromine, are examples of ecthyma. See SKIN, Diseases of.

**ECTOPIA** (ἐκ, out of; and τόπος, a place). An abnormal protrusion or displacement of a part; for example, *ectopia vesicae*, protrusion of the bladder. See ORGANS, Displacement of.

**ECTOZOA** (ἐκτός, without; and ζῶον, an animal).—A term employed by some naturalists to embrace all the external parasites. See EPIZOA.

**ECTROPIUM** } (ἐκ, out of; and τρέπω, I turn).—A condition in which the eyelid becomes everted, so that the conjunctival surface is exposed. See EYE AND ITS APPENDAGES, Diseases of.

**ECTROTIC** (ἐκτιρώσκω, I miscarry).—A term applied to arrest of the course of a morbid process, for example, the development of small-pox. The agent by which the pustule is made to abort, named the ectrotic, may in this instance be a point of nitrate of silver. A coating of plaster, and especially substances which will exclude the light, such as mercurial ointment, or an ointment of lampblack, are likewise employed as ectrotics of small-pox.

ERASMUS WILSON.

**ECZEMA** (ἐκζέω, I bubble up).—SYNON.: Fr. *Eczéma*; Ger. *Eczem*.

**DEFINITION.**—An inflammatory disease of the skin, which in its typical form is associated with the formation of papules and vesicles which quickly burst, and leave a more or less excoriated surface, discharging a gummy serous fluid, which stiffens into a thin crust as it dries. The disease is always attended with itching.

**ÆTIOLOGY.**—Eczema is by far the most common disease of the skin, and is said to constitute about one-third of all the cases of skin-disease. It occurs at all periods of life, from infancy to old age, but is probably rather more common during the first and second dentitions, and in the later period of life, than in youth or middle age; on this point, however, there is some difference of opinion, and in any case, age is not a very constant factor in its development. It is generally admitted to be somewhat more common in males than in females.

The principal causes of eczema may be conveniently divided into three groups: (1) those that are strictly local, such as varicose veins, and the various forms of local irritation; (2) more general causes, such as teething, errors of diet, overwork, and anxieties of all kinds; (3) a constitutional tendency to the disease. It must be admitted, however, that there are cases of eczema for which no definite assignable cause can be found.

With regard to strictly *local* causes, varicose veins are perhaps the most important. Irritants, however, such as tincture of arnica, stimulating plasters and embrocations, often give rise to local attacks of eczema in those who are predisposed to it. Exposure to extreme heat or cold is amongst the well-recognised exciting causes of the malady, which is often a source of annoyance to Europeans living in the tropics. A Turkish bath will sometimes produce a papular eczema such as we also meet with in stokers. The handling of irritating materials, which is incidental to certain trades, occasionally gives rise to local eczema of the hands. Too frequent washing in hard water may be mentioned as a common exciting cause in those predisposed to the disease.

The *general* causes of eczema are of more importance than the local causes, although they are less certain and definite in their action. In children, the process of teething, an injudicious diet, and worms may be mentioned as generally recognised exciting causes of the disease; of these three, injudicious feeding is the most important, and is by no means confined to infancy or childhood. Constipation and a general neglect of the action of the bowels, is another common cause of the perpetuation, if not of the development, of the malady.

With regard to a *constitutional* tendency to the disease, it is, without doubt, common. In some instances, this tendency is so strong that eczema may be said to be always present throughout life, or with but short intervals of freedom. It is generally believed that gouty families and individuals are more liable to eczema than those that have no tendency to gout; the writer does not doubt this fact, but that is very different from the common statement that gout *gives rise to eczema*, for which there is not much foundation.

**SYMPTOMS.**—Eczema is remarkable for the

varying appearance it assumes, according to the acuteness of the inflammation, the stage of the disease, and the parts affected. In an early stage it generally consists of a red and slightly swollen patch; later on, this may be covered with papules and vesicles, which are usually of short duration, to be followed by the development of a moist excoriated surface, discharging a serous or gummy fluid. When the process of healing begins, the patch becomes dry, and covered with thin scaly crusts, which ultimately fall off, and leave the skin in a comparatively healthy condition. Although this is the description of typical eczema, yet the varieties in the course and character of the eruption are so great that they require a brief notice.

There are three principal variations in the development of the eruption: (1) The inflammation may be very acute, and the exudation of serous fluid into the skin and subcutaneous structures so rapid and excessive as to produce great swelling of the tissues. This is especially met with in acute eczema of the face, in which there is sometimes closure of the eyelids, and a complete alteration in the features, so that the patient can be hardly recognised. (2) A very common variation from the normal course of the eruption is the development, from the first, of dry, red, slightly scaly patches, which are never moist, and but little swollen. Eczema of this kind is always attended with much itching, but with no pain or tenderness on pressure. (3) A general eruption of minute red papules over the body and limbs, is another very common form of the disease. The papules usually develop rapidly, and are distributed symmetrically over the body, reminding one, at a little distance, of a scarlatina rash. The eruption generally aborts, dries up, and desquamates without the formation of visible vesicles, though now and then a few may be found amongst the bright red papules.

The various forms or stages of eczema are sometimes indicated by qualifying names; thus the earliest phase consists simply of hyperæmic patches and is called *eczema erythematosum*; later on we may have *eczema papulosum*, and *vesiculosum*; soon the vesicles burst, and leave a raw, discharging, excoriated surface, to which the term *ichorosum* has been applied; when the congestion is great, it is called *eczema rubrum*. The formation of a puriform discharge is indicated by the name *impetiginosum*; and lastly, *eczema squamosum* is applied to the disease in its scaly condition. One or all of these phases of eczema may sometimes be seen in different regions of the body at the same time.

Although the skin of any part of the body is liable to be attacked by eczema, yet it may be said to have a preference for certain regions, as, for example, the flexor surfaces of the limbs, the hands, the scalp, and the points of junction of the skin with the mucous

membranes. In some of these regions, such as the hands, the lips, and the anus, local causes play an important part in the perpetuation, if not in the development, of the malady. Eczema is generally distributed symmetrically, though there are many exceptions to the rule. With regard to subjective sensations, it may be said that they are always present, and form one of the most troublesome symptoms of the disease. In most cases itching is a very characteristic feature; the only exception to this rule is met with in acute eczema, in which the sensations of pain, burning, and smarting for a time mask or take the place of itching; but when the inflammation subsides, itching is sure to arise. In no other affection, except prurigo, is itching so constantly present.

**DIAGNOSIS.**—Eczema is liable to be mistaken for the following diseases: erysipelas, scabies, psoriasis, sycosis, tinea tonsurans, superficial lupus, and some syphilitic eruptions.

*Eczema and Erysipelas.*—Acute eczema of the face, with much exudation into the subcutaneous tissue, is the only form liable to be mistaken for erysipelas. The following points will aid the differential diagnosis: (1) In erysipelas, the eruption is preceded by rigors. (2) The pulse, temperature, and febrile symptoms generally are higher than in eczema. (3) There is almost always headache, and often albuminuria. (4) Erysipelas has a more sharply defined margin, and a smoother and more glazed surface. (5) Erysipelas commonly begins round or below one orbit, and is, more often than eczema, unilateral at first, although, in the end, both sides may be affected.

*Eczema and Scabies.*—These two diseases are often confounded, for the very obvious reason that scabies leads to a kind of artificial eczema. Apart from the use of the microscope, which cannot always be applied, the following considerations will aid the differential diagnosis. Scabies especially attacks certain regions, and when a pimply eruption is met with between the fingers, and on the flexor surface of the wrists, and also at the same time on the lower part of the abdomen, penis, and nates, a very careful examination should be made for other signs of scabies. An examination over the wrist with a common magnifying-glass will often lead to the detection of the scabies cuniculus, looking very like a pin-scratch. The history of the case will also aid the diagnosis.

*Eczema and Psoriasis.*—Dry scaly forms of eczema may be mistaken for psoriasis, though the more sharply defined and raised margin of the latter, with a tendency to form rings, usually makes the diagnosis easy. The development of the eruption on the points of the elbows and just below the knee-caps, is very distinctive of psoriasis.

*Eczema and Sycosis.*—The very chronic

character of sycosis, and the absence of any running exudation, together with its strict limitation to the hairy parts of the face, will generally serve to distinguish it from eczema. In a recent attack the differential diagnosis is difficult, but not of much importance, as the two diseases are very closely allied.

*Eczema and Tinea Tonsurans.*—It is only ringworm of the body that can be mistaken for eczema. A solitary patch of dry eczema-like eruption, spreading at the margin, at once suggests the probability of ringworm. The diagnosis will be rendered almost certain if a narrow margin of the round patch is sharply defined, slightly raised, and of a brighter colour than the other parts. If no treatment has been adopted, the microscope will complete the diagnosis; but if any active remedies have been applied, the microscopic examination is useless.

*Eczema and Lupus.*—Patches of superficial lupus sometimes become covered with scales and eczema-like crusts, which mask the real nature of the disease. A careful examination will, in any doubtful case, lead to a correct diagnosis.

*Eczema and Dermato-syphilis.*—Pustular syphilitic eruption of the scalp may be mistaken for impetiginous eczema. The presence of superficial ulceration, and a peculiar offensive smell, are characteristic of the syphilitic eruption, apart from other signs of syphilis. Dry, cracked eczema of the palm is very common, and is sometimes confounded with a similar condition which is due to syphilis, and often mis-called 'psoriasis palmaris.' This kind of eczema is generally attended with much itching, which is not the case with the syphilitic eruption. Eczema is, moreover, rarely confined to one palm, while the syphilitic eruption is often unilateral. The history of the case will also aid the diagnosis.

**TREATMENT.**—The variations in the character of eczema are so great that it is impossible to lay down rules of treatment that will meet all cases. Some general directions may, however, be given, which will serve as guides, though nothing can supply the place of practical experience.

*Acute Eczema.*—The treatment of acute eczema is simple. In all very severe cases the patient must be confined to bed or the couch. Moderate or free purging with sulphate of magnesium or sulphate of sodium is always indicated, some care being of course required in the case of weakly or elderly people. When the attack is of gouty origin, the purgative treatment may be supplemented by the use of alkalis with iodide of potassium or colchicum, according to circumstances. In the local treatment of acute eczema, all ointments of a stimulating kind should be strictly avoided. If the inflammation is confined to the limbs, water-dressing or a weak lead lotion is often the best application, but it must never be allowed to

get dry. During the day, when the dressing can easily be kept moist, it is better not to cover it with gutta-percha tissue; but at night this plan may be adopted, in order to prevent the lint from getting quite dry. It is difficult to apply water dressing to the head and face, and under these circumstances fuller's earth or starch and zinc powder is a useful application. If, however, this does not suit, the *linimentum calcis*, made with sweet almond oil, may be used; it should be either applied on lint or simply painted on several times daily. Some patients derive great benefit from thin linseed meal poultices, which do not require changing so often as water-dressings, otherwise the principle of treatment is the same in both.

*Sub-acute or Chronic Eczema.*—The *general treatment* of sub-acute or chronic eczema will depend more on the character of the eruption, and the age of the patient, than on the parts affected; the *local treatment*, on the other hand, must be modified to suit the regions attacked. The general treatment would include rest, change of air, diet, and medicine, according to the severity of the case, and other attendant circumstances. If the patient is suffering from gouty symptoms, dyspepsia, or constipation, the plan of treatment should be adapted to meet these conditions, with a considerable probability that it will also be the most suitable treatment for the eczema, which may of course be dealt with at the same time by local means. When, however, the patient is young and in good health, arsenic in moderate doses will be found the most generally useful remedy. In children between the ages of two and five, one-drop doses of the liquor arsenicalis given after meals three times daily is usually enough; it may be combined with alkalis or laxatives or tonics according to circumstances. The routine practice of treating ordinary eczema in young children with iron and cod-liver oil generally ends in failure, especially when the eczema is of an irritable kind. In the pustular forms of eczema, however, iron is useful, and then the arsenic may be combined with the *vinum ferri* or some other preparation of iron. In people of middle age, arsenic is not so generally useful as in children. In the sub-acute irritable forms of eczema, *vinum antimoniale* in small doses, with diuretics, may often be given with advantage instead of arsenic.

In all forms of eczema the greatest attention should be paid to the action of the bowels. The malady is often associated with constipation, and even when this is not the case, some increase in the natural action of the bowels is highly beneficial. The kind of purgative to be used will depend on the age of the patient and other circumstances. In infancy, fluid magnesia in milk is one of the best; in childhood, sulphur powders or lozenges, or mild saline purgatives, are

most suitable; for adults, sulphate of magnesium or sulphate of sodium, given either before breakfast in full doses, or in smaller doses with some tonic two or three times daily, is suitable; lastly, in old age, mild aloetic pills may be given.

*The use of Tar in Eczema.*—For many forms of chronic dry eczema, the various preparations of tar are among the most useful local remedies. They do more to relieve the intolerable itching than any other class of remedies, the chief drawbacks being their disagreeable colour and smell. Before applying tar preparations to eczema, it is always advisable to try the effect in a much diluted form, or over a very limited area; for when applied to unsuitable cases they sometimes produce a great aggravation of the disease. The ordinary tar ointment may be freely diluted with any other ointment, such as zinc ointment, and subsequently the quantity of tar increased or diminished according to circumstances. The tar lotions are less disagreeable than tar ointment; they are made by combining the liquor carbonis detergens (made from coal tar), or the liquor picis compositus (made from vegetable tar) with water, or some simple lotion, such as the ordinary lead lotion. One to four per cent. of the tar solution is usually enough.

*Local forms of Eczema.*—*Eczema of the Scalp.*—Special local treatment is sometimes required when eczema attacks certain regions of the body. On the scalp, when it is attended with much discharge, the hair should be cut and kept quite short. All the scabs should be softened by a poultice, and then removed by bathing with warm water. The head should then be carefully dried, and dressed with an ointment consisting of acetate of lead gr. xv, zinc ointment ʒij, calomel gr. xx, nitrate of mercury ointment gr. xx, vaseline ʒij, benzoated lard ʒss. When the inflammation has subsided, the white precipitate ointment, diluted with an equal quantity of vaseline, may be used. In dry, scurfy eczema of the scalp, the best salve is the red oxide of mercury ointment ʒij, white vaseline ʒvj; this should be applied in small quantities every day. Sometimes when there is much active inflammation, a lotion may be used instead of an ointment until the inflammation has subsided. The most useful are weak sulphate of zinc or boric acid lotions, or carbolic-acid lotion of strength of about one part in a hundred parts of distilled water. Whenever a lotion is used it should never be allowed to get dry; the dressing may be conveniently kept in its place by a light thread or cotton nightcap.

*Eczema of the hairy parts of the face* should be treated very much like eczema of the scalp. If, however, there is pus-formation in the hair-follicles, it is best to remove the hairs that pass through pustules, and allow the pus to escape; then to wash with

weak, strained gruel, and after carefully drying the skin to apply a lotion of calamine and oxide of zinc, so as to dry up the discharge as quickly as possible. The crusts which form, if firmly attached, should be allowed to remain, but when loose from exudation underneath, they should be removed, and, the hair being carefully cut, the surface should then be dabbed with a little medicated wool, and the lotion again applied.

*Eczema of the Anus.*—This is a most troublesome malady, the itching being often out of all proportion to the amount of visible eruption; when this is the case, it is commonly called *pruritus ani*. The most important point in the local treatment of eczema in this region, is always to wash *directly* after the bowels have acted, *without the use of paper*. For this purpose a jug and basin and a very soft old towel should always be kept in the water-closet. After washing, the eczema should be very carefully dried, and some suitable ointment immediately applied. Among the best are the calomel, the diluted oxide of mercury, and the calamine ointments; a very small quantity of the creasote ointment may be advantageously combined with any of these whenever pruritus is the chief feature of the disease. An occasional painting with a solution of nitrate of silver (gr. x ad ʒj) is very useful. Although it is essential to wash directly after the bowels have acted, yet this should not generally be repeated until the bowels act again, too frequent washing being bad for the eczema. A little cotton-wool placed so as to keep the skin on the two sides from touching is very useful.

*Eczema of the Auditory Meatus.*—Any accumulation of crusts should be first removed by syringing with warm water; this should be followed by the use of a tepid sulphate of zinc lotion (gr. iij-vj ad ʒj) several times daily; an occasional painting with a solution of nitrate of silver (gr. viij ad ʒj) is often useful. When the eczema is of the dry kind, citrine ointment diluted with six parts of oil or vaseline, and applied to the inside of the ear carefully with a camel's-hair brush, is the best remedy.

*Fissures in Eczema.*—Fissures are apt to occur in eczema at the corners of the mouth, between the toes, about the anus, and along the lines of flexure in the palm of the hand. The best treatment for these is to carefully paint a solution of nitrate of silver (gr. xv ad ʒj) into the *bottom of the crack*, with a very fine camel's-hair brush, once a day.

*Eczema of the Nipple* is often difficult to cure. It should be *protected from touching the clothes by a shield*, and painted daily with a solution of nitrate of silver (gr. x ad ʒj).

*Chronic Eczema of the Palm* is a most obstinate malady. This arises from the natural thickness of the cuticle, which does

not readily allow the escape of exudation, but cracks and leaves troublesome fissures, especially at the lines of flexure. Moreover, the hands are constantly exposed to the unfavourable conditions of movement and frequent washing. In these cases, if the outer cuticle is much hardened and thickened, it is necessary to remove it. This may be done either by macerating it with a weak lotion of liquor potassæ and distilled water (ʒij ad ʒviij) applied on lint, or by painting it for a few days with a saturated solution of salicylic acid in flexible collodion. When the hard cuticle is removed, the hand should be dressed with the oleate of zinc, or some other soothing ointment. Gloves should be constantly worn, so as to avoid the necessity of washing until the hand is quite well.

*Eczema of the Leg.*—The special indication in the treatment of eczema of the leg is careful bandaging from the foot up to the knee. In some few cases the solid india-rubber bandages are most useful, but they are not always easily borne.

*Pruriginous Eczema.*—Some forms of dry eczema affecting large areas of the body are attended with such intense itching that the patient loses all power to resist the temptation to scratch. As a consequence the skin is torn and lacerated with the nails of the sufferer, which only gives temporary relief. Under these circumstances Professor Unna recommends a kind of gelatine paint made by combining zinc oxide and gelatine, each one part, and glycerine and water each four parts. This is melted when required by placing the jar in hot water, and then painted on with a soft shaving brush. The remedy is rather a disagreeable one, but sometimes useful to prevent scratching in severe cases.

*Diet.*—A careful diet is of considerable importance in the treatment of eczema, especially in children, and in gouty or dyspeptic people. Children suffering from *pustular eczema* require a liberal diet, and especially a little beer or wine, and plenty of fresh meat and vegetables. Even infants with pustular eruptions often require alcohol in small quantities, the best form being from 15 to 20 drops of French brandy in milk two or three times daily according to circumstances. It is the formation of pus which appears to indicate the use of small doses of alcohol. On the other hand, dry irritable eczema in adults is often benefited by a reduction in the usual amount of alcohol. Some kinds of food, such as highly salted meat and fish, sweets—including dried fruits, coffee, and oatmeal, appear to be unsuitable for most kinds of eczema.

*Washing in Eczema.*—Perhaps there is no more common mistake in the treatment of eczema than too frequent washing; indeed, the mistake is a very natural one. In all ordinary cases of eczema, *washing with soap and water must be forbidden*; and

this is most essential when the eczema is healing, and the new, delicate cuticle is forming, for then water macerates and destroys it, and thus the duration of the disease is needlessly prolonged. As a matter of fact, starch or fuller's earth powder keeps the skin quite clean, and also favours the healing process. If washing is absolutely necessary, as it is sometimes in an early stage of the disease where there is much discharge, weak, strained gruel, made with soft or distilled water, is always preferable to soap and water, but even that should not be used often.

*Baths in Eczema.*—It is difficult to lay down any definite rule with regard to the use of baths in eczema. In some forms of eczema, especially in young children, baths do much harm. In gouty people, on the other hand, who suffer from dry chronic eczema resembling psoriasis, a course of mild alkaline baths is often very beneficial. Great discrimination, however, is required in the choice of baths. The summer is the most suitable time of the year for the bath treatment.

ROBERT LIVEING.

**ECZEMA MARGINATUM.** — See *TINEA TRICHOPHYTINA*; and *ERYTHRASMA*.

**EFFUSION** (*e*, out; and *fundo*, I pour). The escape of a fluid from its natural channel or cavity into the substance of organs or the cellular tissue, or from free surfaces. As examples may be mentioned dropsy in its various forms, and effusions resulting from inflammation.

**EGYPT, UPPER.**—A very dry, tonic, winter climate. Mean winter temperature, 62° F. Season, October to March. See *CLIMATE, Treatment of Disease* by.

### ELECTRICITY IN MEDICINE.

The purposes for which electricity is employed in medicine are various. It is used as a stimulant to excite muscular and nervous tissue which is the seat of paralysis or pain, and as a stimulant to the tissues generally; its chemical action may be employed for dissolving tissues and coagulating blood within aneurysmal sacs; and its thermal effects are employed in surgery for heating cauteries. The incandescent electric light has been adapted for the illumination of the throat, as well as of the bladder and other cavities of the body. Electricity is used in its three forms of—(1) *Franklinic, static, or frictional* electricity; (2) *Faradism, i.e.* electricity generated by induction, whether voltaic or magnetic; and (3) *Galvanism or Voltaism*, which owes its existence to chemical action.

**APPARATUS.**—1. *Franklinic electricity*, which is generated by the friction of glass discs or cylinders, and which was formerly much in vogue, may again possibly take its place as a

recognised therapeutic agent. Charcot contends that in some cases of muscular wasting, franklinism will produce a contraction where both faradism and galvanism fail to do so; and in some cases of 'hysteria' also franklinism seems to be of undoubted service.

2. *Faradic batteries* should consist of (a) a coil of insulated copper wire, the ends of which are in connexion with the plates of a galvanic cell. This is called the *primary coil*, and contains a bundle of soft iron wire in its interior. (b) A second coil of insulated copper wire, made of finer wire, and containing a greater number of spirals than the primary, over which it is made to slide; this is called the *secondary coil*. (c) An *interrupter*, capable of interrupting the current automatically and with great rapidity, by means of the constantly recurring magnetic action of the bundle of iron wires in the interior of the primary coil. These batteries should have means of graduating the intensity of the current of either coil, and of including the patient in the circuit of either coil without altering the connexions of the conducting wires. Sometimes the galvanic element is replaced by a large magnet, as in the well-known rotating magneto-induction apparatus.

3. *Galvanic batteries*, when used for therapeutic or electrolytic purposes, should be composed of (a) a large number of small cells of low electromotive force, and as constant in their action as possible. The cells known as the 'Leclanché' are the best. (b) Means of including in the circuit any number of cells at will, so that thereby the intensity of the current may be regulated. (c) Means of opening or closing the circuit at will, and of reversing the direction of the current without altering the position of the current-carriers (rheophores) on the patient's body. This is effected by means of a simple contrivance known as a *key and commutator*. (d) A galvanometer. Practitioners who only make occasional use of electricity should select batteries of the simplest construction; and for rough therapeutic purposes a box of cells provided with screw terminals (one terminal for every third or fourth cell) is all that is necessary. Accessories, such as interrupters, reversers, and galvanometers, should, if needed, be purchased independently and connected with the battery when required. The galvanometer is, for the purposes of exact diagnosis, for physiological experiment, and for electrolytic operations, quite indispensable, as by its use alone are we able to say what strength of current is operating. Not only does the electromotive force of the cells employed vary momentarily, but the resistance of the body varies in the same and in different individuals, so that to say that a current from 'so many cells' has been used is no guide. The galvanometer alone is able to measure the intensity of the current em-

ployed, and these instruments are calibrated to register intensity in milliamperes; and in recording we say that 'the muscle contracted with a current of so many milliamperes,' &c.

Batteries which are required for heating wires and cauteries must be composed of cells of high electromotive force, and as large as is practically possible. The number of cells or elements is of less importance than their size. It is not unusual to have, for this purpose, Groves's or Bunsen's cells capable of containing a pint of liquid each. Accumulators or storage batteries are now much used for this purpose.

The essential and distinctive differences of the two forms of current (galvanic and faradic) will now be described.

**The Galvanic Current.**—The galvanic current is (1) *continuously evolved*; hence it is spoken of frequently as the 'continuous current;' (2) It *flows always in the same direction—i.e. from the positive pole*, which is in connexion with the copper or receiving plate, to the negative pole, which is in connexion with the zinc or generating plate. This fact must be constantly borne in mind, because the action of the two poles is markedly different, and it has been asserted (on very doubtful evidence, however) that the direction of the current in the body, whether towards the nerve-centres or towards the periphery, has an important effect upon the physiological and therapeutical results. (3) It has well-marked *chemical and thermal effects*. This action is most marked at the negative pole, with which, if a moderately intense current be used, heat, redness, inflammation, and even sloughing of the skin may be readily produced. It is therefore always necessary to frequently change the position of the negative pole on the body. (4) It has *electrolytic effects*. When a galvanic current is passed through a conducting compound liquid, decomposition of the liquid results, oxygen (if water only be used) and acids (if saline solutions be used) being evolved at the positive pole, while hydrogen or alkalis, as the case may be, are evolved at the negative pole. Since the human body consists of a mass of cells which contain and are bathed in saline fluids, many of the phenomena observed on passing galvanic currents through the human body, or any part of it, are probably due to this electrolytic action. Faraday called the positive pole the *anode*, and the negative pole the *cathode*, and these terms are frequently employed.

**Induced Current.**—With regard to the induced current, the following points must be remembered. (1) It is *momentary in duration*. (2) Its *direction is constantly changing*, so that, in using it, it is less necessary to distinguish between the poles. (3) Its *chemical, thermal, and electrolytic effects are nil*. (4) It has much greater '*tension*' than the galvanic current—that is, it over-

comes the resistance of the body with far greater ease. (5) It *causes the contraction of healthy muscle* far more readily than the galvanic current. Muscular contractions only occur at the moment of making or breaking a current, and it is mainly to the rapid interruptions of the induced current that its high stimulating power is due. The current of the secondary coil has greater tension, more penetrating power, and greater stimulating power than the current of the primary coil or 'extra-current.' This is due to its being composed of finer wire, and having a greater number of turns.

The stimulating effects of the galvanic current which cause muscular contraction occur only at the moment of making or breaking the current, and not during its continuance, and the stimulating effect of the two poles is different, as may be demonstrated by the 'polar method of investigation,' instituted by Brenner of St. Petersburg. If one rheophore be placed on an indifferent part of the body, as the back, and the other be placed over a nerve-trunk or muscle, we are able by means of the commutator and key to study the action of either pole on nerves and muscles during the making and breaking of the current. With weak currents it is found that contraction ensues only when the stimulating rheophore is negative (cathode), and only on closing the circuit. This is called Cathodal Closure Contraction (C.C.C.) If the strength of the current be slightly increased, we get contraction also when the stimulating rheophore is positive (anode), and the circuit is opened (A.O.C.) Next follows Anodal Closure Contraction (A.C.C.), but Cathodal Opening Contractions (C.O.C.) never occur in healthy muscles with any currents short of those of unbearable intensity.

The galvanic current, unlike the induced current, affects the nerves of special sense. If it be applied in the neighbourhood of the eyes, flashes of light are seen, and blindness has resulted in one case from the incautious application of strong currents to the face. The gustatory nerve is affected in a similar way, and the 'galvanic taste' is perceived when the rheophores are placed on the cheek. The taste is acid with the positive, but metallic and coppery with the negative pole. If the rheophores are held to the ear, rumbling noises are produced, and it is said that stimulation of the olfactory nerve will give rise to a peculiar smell.

Onimus has pointed out a further distinction between the induced and the galvanic current. 'An induced current,' he says, 'only acts during the infinitely short time of its passage, after which everything returns to order. . . . It can never be anything else but a series of slight excitements. With constant currents real excitement is determined only at the times of making and breaking.

. . . It is during the silent period, however, that the principal action of the continuous current makes itself felt.'

It is certain that the rapid interruptions of the induced current, and the strong muscular contractions caused thereby, are capable, if the current be moderately strong, of rapidly and completely exhausting the irritability of a muscle, and, if this fact be not constantly borne in mind, harm instead of good will result from the application of faradism. The galvanic current, on the contrary, possesses remarkable refreshing effects, a fact which has been demonstrated by Heidenhain on frogs, and by the writer on the human subject. It is found that a man can sustain a weight at arm's length far longer than he otherwise could, if a galvanic current be passed through the nerves of the limb. The feeling of fatigue can be removed by the application of the current, and the force of muscular contraction is increased thereby. These facts have important therapeutic bearings.

MODES OF APPLICATION.—To apply electricity we need to have conducting wires and rheophores or current-carriers attached to the battery. The best conductors are made of ordinary telegraph wire, which should be as thick as is compatible with pliability. Telegraph wire is not damaged by moisture, and can be readily connected to all forms of batteries and rheophores, and is therefore economical as well as convenient. Rheophores vary much in design. They should all have insulating handles, and the junction between the conductor and rheophore should be about the middle of its length, so that both conductors may be held in one hand without risk of the metallic junctions coming in contact. The most generally useful rheophore is the sponge-holder. An excellent sponge-holder, which retains the sponge with absolute firmness, is that designed by Kidder of New York. Rheophores should be of different sizes, from a sponge as big as half-a-crown to the pointed extremity of an olive-shaped conductor. They should be made of metal and not carbon, because the latter is too brittle. They may be obtained in the form of discs, balls, points; and of endless design for reaching particular organs and regions, as the eye, ear, larynx, bladder, rectum, and uterus. They are usually covered with wash-leather, and used moist. A wire brush is useful for influencing the skin. The dry hand of the operator, who allows the current to pass through his own body to that of the patient, may be used for the same purpose. It is often convenient to fix one rheophore to the patient's body, which may be accomplished by placing an ordinary sponge on the surface of the body, laying thereupon the naked end of the conducting wire, and securing the whole with one turn of a bandage. If we wish to influence the surface only, we may use one rheophore dry; but if we wish to affect

deeper-lying structures, we must overcome the resistance of the epidermis by thoroughly moistening it with hot salt-and-water. We may use one rheophore dry, and one moist; or we may use as a rheophore a porcelain or gutta-percha vessel containing water, into which the limb is placed.

There are two methods of applying electricity, known as *general electrification* and *localised electrification*. By the former method we pass the current through the entire body or great part of it; it has been employed for many diseases, but its utility is doubtful. By the latter method, which we owe to Duchenne, we seek to influence special nerves, muscles, or organs, and to limit the action of the current strictly to these parts. If we wish to influence a muscle, we may do so either by applying the rheophores directly over the fibres of a muscle, both the rheophores being held in one hand and 'promenaded' over the whole surface of the muscle. This is the *direct* method, and is the method advocated by Duchenne. Or, instead of trying to influence the muscle itself, we may stimulate the nerve supplying it, and so cause the muscle to contract. This is the *indirect* method, advocated by Ziemssen. It is effected by using two rheophores of different sizes. A large rheophore is affixed to an indifferent part of the body, while with a small pointed rheophore an endeavour is made to touch the exact point where the nerve we seek to influence is most superficial. Neither of these methods is to be exclusively adhered to. Certain deep-lying muscles, such as the diaphragm and the supinator brevis, are only capable of indirect stimulation. It will be found also that, in certain diseased conditions, muscles will not respond to stimulation through the nerves, but only to the direct application of the current. When we wish to use the refreshing effects of the current, as in cases of paralysis which are on the road to recovery, or in cases of fatigued muscles, &c., it is advisable to combine the application of the galvanic current with a rhythmical exercise of the affected muscles. Benedict lays it down as a rule that the *locus morbi*, be it brain, spinal cord, nerve, or muscle, should always be included between the rheophores.

DIAGNOSTIC AND THERAPEUTICAL USES.—

1. **Diagnostic Uses of Electricity.**—For purposes of diagnosis, electricity is of undoubted service, since by its means we are often enabled to distinguish between paralysis due to central lesion and paralysis due to peripheral lesion. We are accustomed to speak of a paralysis as 'central' so long as that portion of a nerve-centre is sound from which the nerves supplying the paralysed muscles take origin. Thus in cases of damage to one internal capsule, the spinal cord and the greater part of the brain being healthy, we speak of the case as one of central paralysis. In cases, too, of paraplegia from

local injury, the cord below the injury being healthy (notwithstanding that all mental control is cut off), we speak of the paralysis as central. In such cases of central paralysis we find (a) that reflex stimulation of the muscles is possible, (b) that the muscles undergo but little wasting, and (c) that the irritability of the muscles to faradism is scarcely diminished. We speak of paralysis as due to a 'peripheral' lesion whenever the paralysed muscles are cut off from communication with their nerve-centres, or directly communicate with centres whose physiological activity has been destroyed by disease. In such cases we find (a) that reflex stimulation of the paralysed muscles is no longer possible, (b) that the paralysed muscles waste with remarkable rapidity, and (c) that the irritability of the muscles to faradism is rapidly diminished, and, as a rule, is ultimately destroyed. To establish the fact of diminished irritability to faradism is generally not difficult, and in cases of paralysis affecting one side of the body only it is done by comparing the paralysed muscles with their healthy fellows. We must take care that the current does not vary in intensity, and that it passes through exactly similar lengths of the body for the stimulation of both sets of muscles. It will be found convenient to fasten one rheophore to the middle line of the body (a big sponge tied to the back of the neck answers well), and then, when the patient's limbs are arranged exactly symmetrically, test the healthy muscles first with a small or pointed rheophore, and determine the current of least intensity which will cause contraction. Then the rheophore is to be applied to exactly the same spot on the opposite limb, and, if contraction follows as readily as on the healthy side, we know that there is no diminution of irritability. If, however, contraction do not follow, we increase the strength of current, and so determine to what extent the irritability is diminished, and whether or no it is completely extinguished. We should add that in cases of peripheral paralysis the diminution and extinction of irritability do not supervene immediately on the occurrence of the paralyzing lesion, but only after the lapse of a week or ten days. In paraplegia or other morbid conditions in which paralysis affects both sides of the body it is, of course, impossible to compare a paralysed muscle with its healthy fellow, and in such cases we can only judge of the amount of irritability by experience and mental comparison with previous instances. It is found, in cases of peripheral paralysis, that after complete extinction of faradic irritability the muscles will respond to a slowly interrupted galvanic current, and that not infrequently the irritability of the muscles to galvanism is greater on the paralysed than on the sound side of the body. It sometimes happens that not merely quan-

titative but qualitative changes take place in the irritability of these muscles, and that the Anodal Closure Contraction (A.C.C.) soon becomes very marked, and equals or even surpasses in force the Cathodal Closure Contraction (C.C.C.); and further that the Cathodal Opening Contraction soon becomes more marked than the Anodal Opening Contraction. These reactions, which are supposed to depend upon degenerative changes in the muscle and motor nerve-endings, have been spoken of as the *degenerative reactions*. These quantitative and qualitative changes in irritability are found (1) in some forms of paraplegia due to degenerative changes in the cord; (2) in so-called spinal paralysis both of infants and adults; (3) in traumatic paralysis due to injury of the nerve-trunks; (4) in rheumatic paralysis, that is, paralysis due to 'rheumatic' thickenings of the neurilemma; and (5) in lead-paralysis.

Its occurrence is probably determined by the degeneration of the motor nerve. In one form of 'rheumatic' paralysis—paralysis of the musculo-spinal nerve from cold, as described by Duchenne—the reactions of the paralysed muscle remain normal.

In ordinary hemiplegia the irritability of the muscles remains, as a rule, unchanged. In some cases, however, the irritability is increased in the early stages; and occasionally after the paralysis has lasted some time we find slight diminution of irritability. In some of the conditions confusedly known as progressive muscular atrophy, the irritability of the wasted muscles to faradism remains undiminished to the end.

## 2. Therapeutical Uses of Electricity.

*a. In Paralysis.*—The treatment of paralysis by means of electricity must be conducted rationally and with discrimination. By means of electricity we may attempt to remove the cause of the paralysis, by influencing the nutrition of the parts where such cause is situated, by acting on the sympathetic nerve-branches supplying the walls of the blood-vessels. Thus it is asserted that the absorption of a clot in the brain may be hastened, and that the nutrition of a damaged brain may be improved, by acting upon the cervical sympathetic nerve. To influence the cervical sympathetic we place one rheophore over the superior cervical ganglion (which may be reached by pressing inwards behind the angle of the jaw), and the other on the back, over the first and second cervical vertebræ. The use of such a proceeding is more than doubtful, and in case of any improvement occurring it would be impossible to know to what such improvement ought to be attributed, since the passage of a current across the upper part of the neck must influence many important nerves besides the sympathetic. On the whole, we think that galvanisation of the sympathetic is not to be advised in the early stages of paralysis. Galvanisation of

the sympathetic has been employed in chronic degenerative changes in the brain or cord, but with very doubtful success.

The localised application of the electric current to the paralysed muscles is of undoubted service, and in employing it we should bear in mind the following rules.

1. As to the object of our treatment, we should remember the words of Sir Thomas Watson, 'That our aim is to preserve the muscular part of the locomotive apparatus in a state of health and readiness, until peradventure that portion of the brain from which volition proceeds having recovered its function, or the road by which its messages travel having been repaired, the influence of the will shall again reach and reanimate the palsied limbs.'
2. Always to employ that form of current to which the muscles most readily respond. Thus if the muscles act readily to faradism, then faradism is to be used. In some cases of peripheral palsy we find that contraction follows only on the application of a very strong galvanic current, very slowly interrupted, and accordingly a slowly interrupted galvanic current must be used. As the case improves we shall find that a weaker current produces similar results, and that the muscle contracts with moderately rapid interruptions. And so will improvement gradually take place in favourable cases till faradic irritability and lastly voluntary power are restored.
3. Always to employ the weakest currents which will cause muscular contraction, and never to run the risk of exhausting a muscle by causing a too prolonged contraction. Each muscle should be taken in turn, and be made to contract two or three times in succession, and having gone over the whole of the paralysed muscles seriatim the process may be repeated. An application of this kind every other day is usually sufficient.
4. If the paralysis to the will remain absolute, and if the contractility of the muscles be perfect, we do no good by persevering with electrical treatment. This condition is often met with in hemiplegia. The patient is absolutely helpless on one side, although the paralysed muscles are in no degree wasted, and their irritability remains normal.
5. If the paralysis to the will remain absolute, and if the irritability of the muscles be diminished, then electricity is useful, in so far as it helps to improve the nutrition of the muscles and restore their normal degree of irritability. The normal degree of irritability and nutrition being restored (the paralysis to the will remaining absolute) electrical treatment may be discontinued.
6. If the irritability to both forms of current has completely disappeared, we are not justified in persevering too long, nor in holding out delusive hopes to the patient. Nevertheless, treatment should not be abandoned without a patient trial. [For the treatment of special forms of paralysis by electricity, the reader is re-

ferred to the appropriate sections of this work.]

3. *In Painful Affections.*—The power of electricity to relieve pain is very great. The relief is usually temporary, but in many cases is permanent. Electricity may act by serving to divert the mind from troubles real or fancied, or its counter-irritating effects may serve the same purpose as other counter-irritants whose power to relieve pain is well recognised. Occasionally electricity will give relief when every known remedy has failed, and in such cases we must suppose that it acts by bringing about some change in the nerves themselves by its specific action on nervous tissue. All three forms of electricity are employed for the relief of pain, but the galvanic current will be found the most generally applicable. Some writers insist that the anode (positive pole) shall be applied to the painful spot. Strong faradisation serves in some cases to give relief. The effects of galvanism should be tried in every case of neuralgia, but it is not capable of relieving all cases, and disappointment is not infrequent. Where muscular movements increase the neuralgic pains, a rhythmical exercise of the affected muscles should be conjoined with the galvanism. Headache of all kinds not infrequently yields to electricity; lumbago, sciatica, and those painful muscular conditions which we call 'rheumatic,' are quickly relieved by it. Tinnitus aurium will sometimes yield to the galvanic current when all other remedies have failed.

γ. *In Spasmodic Diseases.*—In the treatment of spasmodic diseases, electricity is of limited utility. Some forms of tremor are relieved by it. Some aggravated cases of writer's cramp have yielded to it when all other remedies have failed, and a few cases of clonic torticollis have received undoubted benefit by its judicious application. Tonic spasm of internal organs, such as the bowel and bladder, has been relieved by the galvanic current.

δ. *In other Diseases.*—In addition to the treatment of diseases of a purely nervous character, electricity has been employed as a remedial agent in diseases whose origin is not so obviously connected with the nervous system. It has relieved the paroxysms of angina pectoris, and the burning pains which accompany herpes zoster. It has been employed in the treatment of many obstinate skin-diseases by American physicians, and Dr. Cheadle has recorded a case in which the dilated vessels in acne rosacea were made to contract by faradisation. Rheumatic gout is said to have been benefited by a 'central' application of galvanism (one pole to the nucha, and the other to the epigastrium). The flow of urine in diabetes has been stated to be diminished by a similar process; and the symptoms of exophthalmic goitre have (it is said) been diminished by

galvanisation of the cervical sympathetic. There is in fact scarcely a disease, from epilepsy to chilblains, in which it has not been alleged that electricity has been of use. In obstetric medicine, for the arrest of *post-partum* hæmorrhage, faradisation is now one of the recognised means to be employed; and it has been of more doubtful service for the rectification of displacements of the uterus. Ovarian pain and tenderness have been relieved by the galvanic current, and amenorrhœa has often yielded to electricity.

ε. *Galvano-cautery and Galvano-puncture.* The chemical and thermal effects of galvanism are largely employed both in surgery and medicine. Its thermal effect has been used for the heating of cauteries; and cauteries so heated have very obvious advantages over all other forms. The chemical effect of the negative pole has been used as a caustic for the destruction of tissues, and tumours of considerable size have, it is said, been 'dispersed' by this means. The treatment of uterine fibroids, as recommended by Apostoli, by passing a current of 250 or more milliamperes by means of a big clay rheophore applied to the abdomen and a special platinum rheophore inserted in the uterus, is a mode of treatment which is occupying the attention of obstetricians, and is still *sub judice*. The same may be said of similar measures applied to cancerous and other tumours. Galvano-puncture has been used in the treatment of hydatid cysts of the liver, but it is at least doubtful whether simple puncture is not quite as serviceable. Galvano-puncture seemed at one time likely to take a recognised position among the means at our disposal for the treatment of aortic aneurysms. Several cases were recorded in which improvement followed this method of treatment, but the success attending it has not on the whole been encouraging, and it has fallen almost entirely into disuse. G. V. POORE.

**ELEPHANTIASIS ARABUM** (ἐλέφας, an elephant).—SYNON.: Fr. *Eléphantiasis*; Ger. *Elephantiasis*.

DEFINITION.—A non-contagious disease, characterised by recurrence of febrile paroxysms, attended by inflammation and progressive hypertrophy of the integument and areolar tissue, chiefly of the extremities and genital organs; and occasionally by swelling of the lymphatic glands, enlargement and dilatation of the lymphatics, and in some cases by the co-existence of chyluria, and the presence in the blood of certain nematode hæmatozoa; together with various symptoms indicative of a morbid or depraved state of nutrition.

ÆTIOLOGY.—Elephantiasis is endemic in India, the Malayan peninsula, China, Egypt, Arabia, the West Indies, and parts of America, chiefly in localities within the influence of the sea air; and it occurs sporadically all

over the globe, excepting, perhaps, in the extreme north and south. Certain conditions of soil and climate, such as humidity, heat, malarious influences, and proximity to the sea-coast, seem to be concerned in producing the disease and influencing its development. Removal from the endemic area frequently checks the disease, whilst return there reproduces it. Elephantiasis affects both sexes, and persons of all ages and conditions of life, but more men suffer from it than women. No race is exempt, but it is much more frequent in dark than in fair races. It occurs at all ages, but is most common in adult and middle life, comparatively rarely beginning in young children or in the aged. Elephantiasis is doubtfully hereditary; but Richards found that of 236 persons, 73 per cent. had one or both parents affected. Various causes are assigned for the disease. Air, water, food, and, as it is common near the sea-coast, eating fish have been frequently credited with producing it. Certain forms of vegetation, and the geological formation of the soil, have also been regarded as predisposing and determining causes. Climate and locality, combined with bad living, are doubtless the real predisposing causes; and it is probable that, as the late Dr. T. Lewis suggested, it may be found to be intimately associated with, if not entirely dependent on, the presence in the blood of certain parasites. No race is exempt from the disease, but, whatever may be the explanation, the white suffer less than the dark races. It does occur occasionally, though very rarely, in the pure European in India, but more frequently in those of mixed descent; it will generally be found that where it occurs in persons of apparently European parentage, there is a mixture, however slight, of dark blood.

ANATOMICAL CHARACTERS.—The hypertrophy of elephantiasis in most cases appears to be simply an increase in the natural elements of the part, the blood-vessels and lymphatics sharing in the growth. In other cases the lymphatics and lymph-spaces are most concerned, giving rise to a condition that has been described as *navoid elephantiasis*, in which the appearance is presented of a soft and fluctuating swelling, which when punctured gives issue to a white or pinkish fluid, very closely resembling chyle. The lymphatic glands also share in the enlargement. In other respects the progress of this variety is like that of the ordinary form of the disease.

The *Filaria sanguinis hominis* is sometimes found in great numbers in the blood of persons suffering from elephantiasis; and the mosquito is considered to be the medium by which the hæmatozoon is transmitted to water, and thence to the human body; but its causal relations to the disease are not absolutely established. See FILARIA SANGUINIS HOMINIS.

**SYMPTOMS.**—The ordinary form in which elephantiasis presents itself is hypertrophy of the integument and areolar tissue of some part of the trunk or limbs, and notably of the legs and genital organs. The skin becomes enormously thickened by hypertrophy of all the fibrous elements of its structure, attended by the deposit of a quantity of albuminous fluid in the interstices of the areolar tissue. The papillæ are prominent and much increased in size. The integument is formed into hard masses or folds, with a rugose condition of the surface, not unlike the appearance of an elephant's leg. The feet and toes are sometimes almost hidden, and the scrotum or labia form enormous outgrowths. The scrotum often attains great weight, and may be accompanied by large hydroceles. Scrotal tumours have been removed weighing upwards of 100 lbs.

The onset of elephantiasis is frequently violent and attended with great suffering. There is high fever; intense pain in the lumbar region, groin, spermatic cords, and testes, which become swollen; while acute hydroceles form. These symptoms are often attended with sympathetic vomiting, nausea, and rapid erythematous swelling of the external parts; and, if the extremities be attacked, the swelling may be tense and painful, accompanied by much effusion into the areolar tissue. The surface of the integuments is much inflamed, and sometimes discharges a serous ichor or chyle-like fluid, according to the extent to which the lymphatics are engaged in the particular case. The great tension and swelling of the spermatic cords are apt to dilate the abdominal rings so widely, that after recovery the patient may suffer from hernia.

In some cases of elephantiasis the integuments are also the seat of a dilated and turgid condition of the lymphatic vessels, which during the periods of vascular excitement, when the febrile attacks occur, give way and discharge a chyle-like fluid; in other cases the surface temporarily assumes a herpetic condition, which exudes an acrid and offensive serous fluid. See *CHYLURIA*.

Elephantiasis not infrequently occurs without much or any obvious injury to, or disturbance of the general health during the intervals between the febrile attacks, which in some cases are few and slight. The appetite, spirits, and strength are good, the functions are all normally performed, and the only inconvenience is that due to the size and weight of the outgrowth. On the other hand, it is frequently quite the reverse: the rapidly recurring febrile attacks, pain, exhaustion, suffering, and visceral complications induce a state of cachexia and debility sometimes so serious as to render even surgical interference impracticable. Withal, hepatic and splenic enlargements do not as a rule result from the persistence of the elephantoid fever alone;

though not infrequently, as a more direct result of malarious poisoning, they seriously complicate the evils of the sufferer's condition. Albuminuria, as well as chyluria, is occasionally present.

In some cases, after the outgrowth has attained a certain bulk, it ceases to grow altogether, or increases slowly and insidiously without febrile disturbance, and in such cases the general health remains good. But there is generally a tendency to recurrence of the fever once or twice a month, when the parts affected become tense, hot, painful, and swollen, and often discharge a serous or lymph-like fluid, which may be acrid and offensive. Some tumours, on the other hand, are very slightly, if at all, so affected, and remain perfectly dry. In all cases, however, some growth goes on; and even when, as occasionally happens, fever has ceased to recur, there may be a gradual, but slow and painless, increase of the hypertrophy. The greatest variety and uncertainty obtain in the duration and progress of the growth: sometimes it is very rapid, at other times it is slow, with intermissions of activity and indolence of development. The disease elsewhere than in the genitals, unless it be accompanied by exhaustion and debility, causes no failure in the generative powers in either sex. Women may have a tendency to miscarry when suffering from elephantiasis.

**COURSE, DURATION, AND TERMINATIONS.**—According to Richards, the average duration of the disease, as deduced from the observation of 636 cases, was 11½ years; and he notes that the earliest age was nine years, whilst the latest at which he observed it was eighty years. It appears from this that the disease has little influence in shortening life.

**PATHOLOGY.**—The outgrowths in elephantiasis are the local expressions of a constitutional disease, and are not to be regarded merely from their local point of interest. They are the result of certain climatic influences whose exact nature is not at present determined; though, considering the geographical range of the area where the disease is endemic, it seems probable that, whatever other cause may be at work, the so-called malarious influences play some part in its production.

The researches of the late Dr. T. Lewis into the pathology of chyluria in India, and his discovery of certain hæmatozoa in the blood of those affected with that disease, coupled with the fact that the subjects of chyluria and hæmatozoa are also frequently, if not always, affected by elephantiasis with its febrile paroxysms, hypertrophied integument, and lymphatic disturbance, are very suggestive of a community of origin of these morbid conditions. Dr. P. Manson's investigations into the connexion of the mosquito with the transmission of the filaria are also most important and interesting.

**TREATMENT.**—Little has yet been done by constitutional treatment in cases of elephantiasis. Remedies useful during the febrile paroxysms have little power in preventing recurrence of, or in checking the disease. Iodine, combined with quinine, arsenic, and iron, has been found useful to a certain extent. During the febrile state salines, diaphoretics, and such remedies as are needed during the pyrexial state of malarious fevers, are indicated. Opium may be necessary to relieve the intense pain which often accompanies the onset of the stage of excitement. When the febrile stage has passed, quinine is useful, which, if anæmia exist, should be combined with iron. The local application of iodine, in such forms as the iodide of lead or biniodide of mercury ointment, has been thought useful; but as this is generally combined with pressure in the recumbent posture, the benefit is probably due to the latter. Such measures, along with improved hygienic conditions, may no doubt control the progress of the disease and relieve suffering. No remedy, however, is so potent as change of climate, by removal from the endemic site of the disease. This, if effected in the earliest stages, may completely arrest the disease, and perhaps even disperse any incipient structural change. This has been observed in the rare cases in which elephantiasis occurs in Europeans, who, on returning to Europe, have after a time lost the disease, and almost, or entirely, any hypertrophic changes that may have occurred. Natives of India improve if they leave the endemic area during the early stages, and go and reside in other and drier localities. However, when the hypertrophy is advanced, the paroxysms of fever are still liable to recur, even when the climate is changed, though with less violence.

*Surgical treatment*, when the hypertrophy is advanced, is often most successful in relieving the sufferer, not only of the local trouble, but also of the fever. Tumours of the genital organs, sometimes of enormous size, are now removed with complete success and comparatively small mortality. Before commencing the operation, especially in the case of a large scrotal tumour, it is well to drain it of blood by placing the patient on his back, and elevating the tumour on the abdomen for an hour or so, during which time pressure by a bandage (a modification of Esmarch's) may be tried, and cold (ice) may be applied. During the operation, the application of a whipcord ligature drawn tightly round the neck of the tumour also prevents loss of blood.

The removal of a scrotal tumour is effected by incisions along the course of the cords and the dorsum penis. The cords, testicles, and penis are turned out by a few touches of the knife, and then reflected and held up on the abdomen, while the mass of the tumour is

rapidly swept away by a few bold incisions in the perinæum. The numerous venous and arterial bleeding points should then be arrested, and the wound dressed with antiseptic applications. No attempt should be made to preserve flaps of integument either for the penis or testes. It is unnecessary, and almost certain to be followed by recurrence of the disease. The process of cicatrisation goes on rapidly, and in from two to four months all is closed in by cicatricial tissue, which gradually perfects itself, and has no liability to become the seat of a return of the disease.

JOSEPH FAYRER.

**ELSTER, in Saxony.**—Alkaline sulphated waters. See MINERAL WATERS.

**EMACIATION** (*emacio*, I make lean). Wasting or loss of flesh. The term is applied both to the process of wasting and to the condition that results therefrom. See ATROPHY; and ATROPHY, GENERAL.

**EMBOLISM** (*ἐμβολισμ*, a plug).—SYNON.: Fr. *Embolie*; Ger. *Embolie*.

**DEFINITION.**—The arrest in the arteries or capillaries of some solid body, which has been carried along in the course of the circulation.

**PATHOLOGY.**—Emboli usually consist of portions of fibrin derived from thrombi of the veins or heart, or of vegetations detached from the cardiac valves. They may, however, be formed by fragments of tumours which have grown into the blood-vessels, or of other foreign bodies, including fat, which have obtained entrance into the circulation.

The effects of embolism may be divided into two classes: First, those which are caused by the arrest of the circulation; and secondly, those which are due to any specially irritating properties of the embolus.

1. The embolus may, first, be supposed to consist of some *indifferent* substance not possessing any irritating qualities. The effects which may then be caused by arterial embolism are mainly these: First, a transient anæmia of the territory supplied by the blocked artery. This may pass away without leaving any permanent consequences. Secondly, necrosis of this territory. This may be either sudden, in the form of gangrene; or more gradual, in the form of softening or withering. Thirdly, the formation of a *hæmorrhagic infarction*, that is, congestion of the territory, followed by extravasation of blood into the tissues, and so the formation of a firm, solid patch of a dark red colour, usually of a wedge shape, with the apex towards the embolus, and the base towards the periphery. In very soft organs, as the brain, the extravasation may break down the tissue and cause the ordinary phenomena of an apoplectic clot. These hæmorrhagic infarctions undergo various subsequent changes. Usually a process of degeneration sets in;

the blood-pigment passes through its familiar transformations; the patch changes from dark red to tawny and yellow, undergoes molecular disintegration, shrinks away, and ultimately leaves a depressed fibrous patch, in which the remains of the altered blood, crystals of hæmatoidin, &c., may often be recognised. Sometimes the patch softens down into a puriform fluid, which may become surrounded by a fibrous capsule, and ultimately dry up, or even calcify. When recent, these patches are usually surrounded by a halo of congested vessels.

The cause which determines these different results of arterial embolism is, in the main, the anatomical arrangement of the blood-vessels. Supposing the embolus to be lodged in an artery which gives off anastomotic branches between the seat of the embolus and the final capillary distribution, the effect in most cases will be transient anæmia, the collateral channels will enlarge, and the circulation will be again restored. A thrombus will form on the embolus and will extend back to the next arterial branch, and the changes described in the article on thrombosis will take place in it (*see* THROMBOSIS). If the blocked artery be of large size, and supply important organs, the symptoms of temporary arrest of function of the part supplied by the artery will follow, as transient paralysis, dyspnœa, coldness of the extremities, &c., according to the artery affected. Should, however, the artery be small, and not supply important organs, no symptoms whatever will be caused; and this is the case in the majority of embolisms. Supposing, however, the artery is what Cohnheim calls a *terminal* artery—*i.e.* one which gives off no anastomotic branches between the embolus and the final capillary distribution, and that the capillary anastomosis with other arterial territories is insufficient to supply a collateral circulation, and that the presence of valves prevents the reflux of blood into the territory from the veins, it is manifest that the embolism must completely cut off the blood-supply, and consequently, in some form or other, cause necrosis of the territory.

The network of anastomosing channels is, however, so close in most parts of the body that, in order to produce this effect, it is necessary either that the main artery of the part be obstructed, or else that there be multiple embolisms blocking up at the same time several arterial branches, and so stopping the channels of collateral circulation.

The mode in which the hæmorrhagic infarction is produced is still a subject of dispute. According to Cohnheim, whose views until recently were generally accepted, the hæmorrhage is due to a reflux from the veins into the territory supplied by the blocked artery. This first causes congestion, and then extravasation, in consequence of impairment

of nutrition of the walls of the blood-vessels for the integrity of which the circulation of the blood is essential. According, then, to Cohnheim, in order to produce the phenomena of the hæmorrhagic infarction it is necessary that the artery be a terminal one—*i.e.* one which gives off no anastomotic branches for some distance before its final capillary distribution, and that the veins be not furnished with valves. These conditions are met with in the spleen, the kidney, the brain, certain branches of the pulmonary artery supplying surface lobules, and the central artery of the retina; and on these grounds he accounts for the frequent occurrence of hæmorrhagic infarctions in these organs, though there is no reason to suppose that, with the exception of the lungs, embolisms are more frequent in them than in other parts.

The more recent researches of Dr. M. Litten, *Zeitschrift für klinische Medicin*, vol. i. p. 189, render, however, these views no longer tenable. He shows by experiments on the kidney, spleen, lung, &c., that if the blocked artery be a strictly terminal one—*i.e.* one whose area of distribution has no other arterial supply, the phenomena of the hæmorrhagic infarction do not occur, even though the vein have no valves; and under other circumstances that the infarction takes place although the vein has been ligatured; hence the cause of the infarction cannot be venous reflux. Thus, if both the renal artery and vein be ligatured, infarction of the kidney takes place, the kidney receiving a sufficient collateral supply of blood from other sources; but if the capsule be first stripped off, and the kidney left attached only by the renal artery and vein, no infarction takes place, though the vein is left pervious. Similar results were obtained in other organs. Hence it would seem evident that the congestion and infarction following embolism are produced by an afflux of arterial blood into the territory from collateral channels. Should these be numerous, and should small arteries open directly into the anemic territory, the circulation will soon be restored, and no infarction will take place; should, however, the communication be imperfect, and chiefly by means of capillaries, a congestion of the territory, leading to diapedesis, and infarction will result, the *vis a tergo* being insufficient to propel the blood onwards into the veins.

Litten has also shown that the vessels in which the circulation has been arrested retain their integrity much longer than was supposed by Cohnheim; and that in the kidney, long before the vessels suffer, necrosis of the epithelium takes place, the nuclei of the cells disappear, their protoplasm coagulates, and they become converted into swollen hyaline masses (*coagulation necrosis*), which have a remarkable tendency to calcification. Hence the wedge-shaped white embolisms often seen

in the kidney are not produced by decolorisation of hæmorrhagic infarctions, but are simply the result of the necrosis of the epithelium; and the halo of injection which is often seen to surround them is due to inflammatory congestion caused by the presence of the necrosed patch.

This explanation of the mode of production of the hæmorrhagic infarction is more closely in accord with the view originally propounded by Virchow, who regarded the hæmorrhage as due to collateral fluxion.

2. We have now to consider the effects of emboli which possess irritating or *poisonous* qualities, such as those derived from the puriform softening of venous thrombi in cases of septic inflammation. The mechanical effects will be the same as those of the previous class; but, in addition, these emboli set up a suppurative inflammation in their vicinity, quite independent of any obstruction of the circulation. Hence it is that we meet with pyæmic abscesses, as the result of infecting emboli, in all parts of the body, while the effects of obstructed circulation are, for the most part, confined to certain organs. Thus the liver is very frequently the seat of embolic abscesses, while hæmorrhagic infarctions do not occur there. In the lung, where in parts terminal arteries are found but for the most part there is free anastomosis, the two processes are often seen side by side. The different effects of these two classes of embolism are very manifest in the capillaries. Simple emboli, of such small size as to become first arrested in the capillaries, either cause no permanent change at all, or, at most, produce a punctiform hæmorrhage. Infecting emboli, on the other hand, give rise to the miliary abscesses so often seen in pyæmia.

W. CAYLEY.

**EMESIS** (ἐμέω, I vomit).—A synonym for vomiting. See VOMITING.

**EMETICS** (ἐμέω, I vomit).—SYNON.: Fr. *Émétiques*; Ger. *Brechmittel*.

**DEFINITION.**—Agents that produce vomiting.

**ENUMERATION.**—Copious draughts of Luke-warm Water, Mustard, Sulphate of Zinc, Sulphate of Copper, Carbonate of Ammonium, Common Salt, Alum, Chamomile, Tartar Emetic, Ipecacuanha, and Apomorphine.

**ACTION.**—The act of vomiting consists in the simultaneous spasmodic contraction of the diaphragm and abdominal muscles, and relaxation of the cardiac orifice of the stomach, so that its contents are expelled. When the diaphragm and abdominal muscles contract, but the cardiac orifice remains closed, so that the contents of the stomach cannot escape, the expulsive efforts are termed *retching*. The nervous centre which regulates these movements is situated in the medulla oblongata; and it may be excited either directly by the action upon it of drugs

carried to it by the blood, or reflexly by irritation of various nerves. The drugs that act directly upon it have the same action, whether they are introduced immediately into the circulation or absorbed by the stomach. They may thus produce vomiting and evacuation of the stomach without being taken into the stomach at all, and on this account they are termed *indirect* emetics, although they act directly upon the vomiting centre. Such are ipecacuanha, apomorphine, and tartar emetic. Similarly the drugs that excite it reflexly are still termed *direct* emetics, because they are applied directly to the stomach. Such are the sulphates of zinc, copper, and aluminium; carbonate of ammonium; salt; mustard; and chamomile, which irritate the nerves of the stomach. Ticking the fauces with a feather, or with the finger, also excites reflex vomiting, and may be adopted either alone, or in order to aid the action of other emetics. The terms *direct* and *indirect*, therefore, as applied to emetics, relate to the stomach, and not to the centre for vomiting.

Direct emetics, as they stimulate the nerves of the stomach only, have little action except that of simply exciting vomiting. The indirect emetics, which excite vomiting by their action on the medulla oblongata, act also on other parts of the nervous system, and cause secretion of saliva, secretion of mucus from the œsophagus, stomach, and bronchial tubes, and perspiration. They also cause much nausea, depression of the circulation, and loss of nervous and muscular power. Further, the vomiting they induce is more continuous and violent, and often expels the contents of the gall-bladder, causing part of the bile to flow into the stomach, and be thus evacuated.

**USES.**—Emetics are employed to remove the contents of the stomach under various circumstances. Firstly, when the food is causing irritation, and not undergoing proper digestion, as, for example, in dyspepsia or sick-headache; and in such cases large draughts of lukewarm water, of mustard and water, or of an infusion of chamomile are usually found beneficial. Secondly, in cases of poisoning; and here mustard, sulphate of zinc, and sulphate of copper are best, as they empty the stomach most quickly and effectually. Thirdly, to cause the expulsion of bile from the gall-bladder, or remove bile from the body, in biliousness, fevers, and ague. When the bile-duct is stopped by a small gall-stone, the pressure exerted on the gall-bladder during vomiting has been known to cause the expulsion of the calculus. In biliousness, excess of bile is more readily removed by vomiting than by purging, as there is no opportunity for the bile to be absorbed on its way from the gall-bladder to the mouth, whereas it may undergo absorption on its passage through the intestines. It is supposed

by some that various poisons circulate occasionally in the bile, such as the malarious poison which occasions ague, and possibly certain septic poisons which give rise to fevers. The advantage of emetics in ague is undoubted, as it can certainly sometimes be cured by them without quinine, and the action of quinine is always aided by their use. They have also been recommended in the early stages of continued fevers. In such cases tartar emetic or ipecacuanha is most serviceable. Fourthly, to cause expulsion from the air-passages of false membrane in croup or diphtheria, or of secretions in bronchitis and phthisis. For these purposes ipecacuanha is the emetic most frequently chosen; but if it do not act rapidly in croup, sulphate of zinc or sulphate of copper may be employed, or a teaspoonful of powdered alum and honey. In cases of either croup or bronchitis, where there is great depression of the circulation, carbonate of ammonium may be used with advantage, as it not only causes vomiting, but at the same time stimulates the circulation.

T. LAUDER BRUNTON.

**EMMENAGOGUES** (*ἔμμηνα*, the menses; and *ἄγω*, I move or expel).

**DEFINITION.**—Emmenagogues are remedial agents which stimulate or restore the normal menstrual function of the uterus, when it is irregular or absent.

**ENUMERATION.**—Emmenagogues may be either *indirect*, as Iron, Strychnine, and other tonics, Warm Hip-baths, Leeches, Mustard, Aloetic purgatives, &c.; or *direct*, as Rue, Borax, Savin, Myrrh, Cantharides, Guaiacum, Apiol, Quinine, Digitalis, and Ergot—most of which, when given in larger doses, produce abortion, and are called *ecbolics*. The most efficient means, however, of obtaining this last-named action are those of a mechanical nature, so well known to obstetricians, and directed either to the actual rupture of the membranes, or to their separation from the cervix.

**ACTION.**—The *indirect* emmenagogues act by improving the quality of the blood, giving tone to the nervous system, or irritating adjacent parts or organs, from which a stimulating influence is conveyed by reflex action to the womb.

The *direct* drugs in moderate doses gently stimulate the uterus, thus promoting the menstrual flow, or even checking it when in excess; but when further pushed they may cause powerful contraction of the unstriped muscular fibre, of which its walls are mainly composed. Ergot is believed to act either directly on the muscular tissues themselves, or through the intermediate intervention of some central or peripheral nervous influence.

**USES.**—Checked or retarded menstruation frequently results from anæmia or general

debility, and the indirect emmenagogues will under these circumstances usually effect a cure. If, however, the case prove more obstinate, one or more of the direct emmenagogues will often restore the suspended function. Should even this do no good, some mechanical impediment probably exists, or some altered physical condition of the womb which mere drugs cannot rectify.

ROBERT FARQUHARSON.

**EMOLLIENTS** (*emollio*, I soften).—**SYNON.**: Fr. *Émollients*; Ger. *Erweichende Mittel*.

**DEFINITION.**—Substances that soften and relax the parts to which they are applied.

**ENUMERATION.**—The principal emollient applications are:—Warm water, Steam, Poultices made of substances which retain heat and moisture, for example, linseed-meal, bread, bran, flour, oatmeal, and figs; Fatty substances, as linseed, olive, almond, and neat's-foot oil, lard, and suet; Spermaceti, Wax; Soap Liniment and other liniments; Glycerine; Paraffines; and Lanolin. To these may be added such substances as do not properly relax the tissues, but protect the surface from irritation, such as White of Egg, Gelatine, Isinglass, Collodion, and Cotton-wool.

**ACTION.**—Emollients relieve the tension and pain of inflamed parts by their action both upon the blood-vessels and upon the tissues themselves. They cause all the contractile tissues to relax and dilate, and thus, lessening pressure upon the nerves of the part, they relieve pain. They soften superficial parts by supplying them with either fat or moisture, and by increasing the supply of blood. In this way they prevent the skin from cracking after exposure to cold. When the cuticle is lost they form a covering, under which the skin may heal; and they prevent the injurious consequences of friction from without.

**USES.**—Fatty emollients are used to prevent the skin or mucous membranes from cracking; to prevent irritation or ulceration between parts constantly in contact, as on the limbs of children near the joints; to prevent bed-sores; to aid the healing of blisters; or in skin-diseases, such as eczema. They are also used, especially in the form of linimentum calcis, as applications in burns and scalds, for which purpose such substances as cotton-wool are likewise frequently employed. Mucilaginous substances are useful, when swallowed, to relieve pain and irritation in the throat, and to lessen irritable cough; and such substances as figs are employed to protect the intestines from injury by hard and pointed substances which have been swallowed. Warmth and moisture are applied in the form of poultices to the surface in pustules, boils, carbuncles, and deep-seated inflammation of the limbs, and

in inflammation of the internal organs (*see* POU LTICE). In the form of vapour they are useful in inflammation of the air-passages. *See* INHALATIONS, Therapeutic Uses of.

T. LAUDER BRUNTON.

**EMPHYSEMA OF LUNGS.**—*See* LUNGS, Emphysema of.

**EMPHYSEMA, SUBCUTANEOUS** (*év, in;* and *φύσα, wind*).—*SYNON.*: Fr. *Emphyseme*; Ger. *Emphysem*; *Windgeschwulst*.

**DESCRIPTION.**—Subcutaneous emphysema is the distension of the spaces of the areolar tissue with air or any other gas. There is thus produced a swelling, in slight cases affecting a very limited area, in extreme cases extending to the subcutaneous tissue of the whole body. Unless the tension is great, the swelling is slightly lobulated; it is elastic, and although the finger sinks readily into it, no lasting impression is left. When the area affected is small, the gas can be driven in any direction by the pressure of the hand. On palpation a peculiar fine crepitation is felt, which is absolutely diagnostic. On percussion there is superficial resonance, the note resembling that obtainable from a bladder loosely filled with air. Unless the gas causing the emphysema is the product of decomposition of gangrenous tissues, as in spreading gangrene, there is no redness of the skin. The swelling usually forms rapidly, and may extend in a few minutes over the greater part of the body. In such cases it is most marked where the subcutaneous tissue is lax. In the face the features are obliterated, and the eyes closed by the swelling of the lids. The scrotum and penis become enormously distended.

**ÆTIOLGY AND PATHOLOGY.**—Wound of the lung from a broken rib or from a stab is the most common cause of subcutaneous emphysema. If from a stab, it can only occur when the opening in the pleura and that in the skin no longer correspond with each other, in consequence of an alteration in the position of the patient, or when the wound has been artificially closed. When from wound of the lung, it may occur with or without pneumothorax. Nothing is more common than to find a limited emphysematous swelling round a fractured rib, without any signs of air in the pleural cavity. This arises either from adhesions existing between the parietal and visceral layers, or from the escape of air being very limited. In severe cases with pneumothorax the mechanism of the production of emphysema is as follows: A wound in the lung always allows air to pass from it readily, but from the way in which the soft pulmonary tissue falls together, no amount of force can drive air through the wound in the opposite direction. It thus acts

somewhat like the valve of an air-pump. The first effect of the escape of air into the pleural cavity is to cause collapse of the lung. As the chest expands with each inspiration air rushes from the wound in the lung into the pleural cavity; as it contracts in expiration, the air, being unable to pass back by the wound, is driven through the opening in the parietal pleura into the subcutaneous cellular tissue. In such cases there is gradually increasing dyspnoea, with great distension of the subcutaneous cellular tissue; and unless relief is given, the patient dies asphyxiated.

Emphysema occasionally occurs from rupture of some of the air-vesicles during a violent expiratory effort. Dr. Walshe states that this accident has happened from 'the efforts in parturition, defecation, raising weights, coitus, violent coughing, paroxysms of rage, excessive laughter, and hysterical convulsions.' The air usually escapes first into the cellular tissue between the lobules of the lung, giving rise to the condition known as *interlobular emphysema*. It then finds its way into the mediastinum, and thence to the root of the neck. Interlobular emphysema gives rise to intense dyspnoea, and has been known to cause sudden death. Emphysema has also been seen as a consequence of ulceration of the trachea, and in a few very rare cases as the result of ulceration proceeding from a cavity in the lung through the adherent pleura and intercostal muscles to the subcutaneous cellular tissue.

Localised emphysema of the face is a symptom of fractures implicating the antrum.

Emphysema of the flanks is an occasional symptom of rupture of the third part of the duodenum, behind the peritoneum, and of perforation of the cæcum at its posterior part.

Emphysema of the perinæum and scrotum may arise from a wound of the bowel in the administration of an enema.

In non-penetrating wounds of the thorax and abdomen, a small quantity of air may find its way into the areolar tissue in the immediate neighbourhood, in consequence of the movements of respiration. In compound fractures emphysema is often found extending some distance above and below the wound, if the patient has been carried some distance and the injured limb much shaken.

Emphysema from the gases produced by decomposition is only seen in cases of rapidly spreading moist gangrene—*emphysematous gangrene*.

**PROGRESS AND TERMINATIONS.**—The effects of emphysema differ with the source of the gas. When the air comes from a superficial wound of the lung, it has no tendency to cause decomposition of the effused blood with which it may come into contact. Thus, in surgical cases, no evil consequences result from emphysema around a simple fracture of

a rib. This is explained by the fact that the gas in the air-vesicles is absolutely free from solid particles of any kind, including micro-organisms, as shown by Tyndall's experiment, in which the residual air, in forced expiration, makes a gap in the beam of an electric light when breathed across it. On the other hand, air admitted from without, as in a compound fracture, tends to favour the decomposition of the effused blood, and renders treatment by occlusion or by antiseptic dressing difficult and uncertain. In ordinary cases the effused air is rapidly absorbed without causing inconvenience of any kind. If the amount of air in the tissues be very great, and the case be complicated by pneumothorax, fatal dyspnoea may occur, unless relieved by treatment.

**TREATMENT.**—The swelling itself requires usually no treatment, the gas being absorbed without difficulty. If it is complicated by pneumothorax, or if the dyspnoea be such as to threaten death, the wound, if one exists, must be opened up; or, if there is none, a free opening must be made into the pleural cavity. If the swelling be such as seriously to inconvenience the patient, a few punctures may be made with a triangular needle. Emphysema from intestinal flatus is always limited, and requires no treatment beyond that applicable to the cause of the escape of gas.

MARCUS BECK.

**EMPIRICAL** (ἐν, by; and *πέιρα*, experience).—This term is applied to treatment founded on experience, as contrasted with *rational*, which is founded on scientific reasoning. See DISEASE, Treatment of.

**EMPROSTHOTONOS** (ἐμπροσθεν, forwards; and *τείνω*, I stretch).—A bending or drawing forwards of the body, due to tonic contraction of the muscles, observed in some cases of tetanic convulsions. See TETANUS.

**EMPYEMA** (ἐν, in; and *πύον*, pus).—Strictly speaking, this term signifies a collection of pus within the cavity of the pleura, but it is often conventionally used to denote any inflammatory effusion in that situation which has assumed a chronic character. See PLEURA, Diseases of.

**EMS, in Germany.**—Thermal muriated alkaline waters. See MINERAL WATERS.

**ENCEPHALITIS** (ἐγκέφαλος, the brain). Inflammation of the brain and its membranes; or, more properly, inflammation of the brain-substance itself. See BRAIN, Inflammation of.

**ENCEPHALOCELE** (ἐγκέφαλος, the brain; and *κύλη*, a tumour).—A hernial protrusion of a portion of the brain-substance through an opening in the skull, which may be either congenital or the result of accident, of surgical operation, or of disease. See BRAIN, Malformations of.

**ENCEPHALOID** (ἐγκέφαλος, the brain). A form of cancer, so named on account of its obvious resemblance to brain-tissue. See CANCER.

**ENCHONDROMA** (ἐν, in; and *χόνδρος*, cartilage).—A new-growth consisting of cartilaginous tissue. See TUMOURS.

**ENCYSTED** (ἐν, in; and *κύστις*, a bladder).—Contained within a cyst. A term applied to new-growths or collections of fluid thus enclosed, or limited by adhesions.

**ENDARTERITIS** (ἐνδον, within; and *ἀρτηρία*, an artery).—Inflammation of the internal coat of an artery. The disease is generally chronic or subacute, rarely acute. Two special forms of endarteritis have been described—namely, *endarteritis deformans*, or atheromatous disease (see ARTERIES, Diseases of; and ATHEROMA); and *sypilitic endarteritis*, which frequently affects the vessels of the brain. See SYPHILIS; and BRAIN, Vessels of, Diseases of.

**E endemic** (ἐν, in; and *δῆμος*, a people). This term is applied to diseases that prevail in particular localities or districts, and which are due to special ætiological conditions existing there. See DISEASE, Causes of.

**ENDERMIC MEDICATION** (ἐν, in; and *δέρμα*, the skin).—Fr. *La Méthode Endermique*; Ger. *Intracutane Arzneiapplication*.

**DEFINITION.**—The method of using remedies either by rubbing them into the skin or by sprinkling them on a surface which has been previously denuded of its epidermis.

Endermic medication was strongly advocated and practised by Lembert, Valleix, Trousseau, Anthony Todd Thomson, and others, but it has almost, if not entirely, given place to hypodermic injection, (1) because the endermic method is the more painful; (2) because it is slower in action—thus, Trousseau found that twelve minutes were required for one-sixth of a grain of morphine endermically administered to take effect, whereas, hypodermically, the action of the same dose is observed in less than one minute, in fact, almost immediately; (3) because in many parts of the body endermic medication is totally inapplicable.

**METHOD AND USES.**—The epidermis should first be detached either by some ordinary vesicant, such as cantharides plaster, or by the application of a cautery. The drug to be used is then laid on the raw surface in the form of powder rubbed up with starch, sugar, sulphate of sodium, or some other unirritating substance, paste made with water or thin mucilage, or ointment. In this way, neuralgia, sciatica, and other painful affections may be treated with the morphine salts in doses of

one-sixth of a grain and upwards; local paralyses and other nerve-troubles with strychnine in doses of one-fiftieth of a grain and upwards; and many other alkaloids may be used in the same way in various diseases.

A. S. CURRIE.

**ENDOCARDITIS** (*ἔνδον*, within; and *καρδιά*, the heart).—Inflammation of the lining membrane of the heart. See HEART, Inflammation of.

**ENDOGASTRITIS** (*ἔνδον*, within; and *γαστήρ*, the stomach).—Inflammation of the mucous membrane of the stomach. See STOMACH, Diseases of.

**ENDOMETRITIS** (*ἔνδον*, within; and *μήτηρ*, the womb).—Inflammation of the lining membrane of the uterus. See WOMB, Diseases of.

**ENDOPERICARDITIS**.—Inflammation of the endocardium and pericardium together. See HEART, Inflammation of; and PERICARDIUM, Diseases of.

**ENDOSCOPY** (*ἔνδον*, within; and *σκοπέω*, I look).—DEFINITION.—The inspection of internal surfaces. Taken inclusively, this definition comprises ophthalmoscopy, otoscopy, laryngoscopy, rhinoscopy, urethroscopy, cystoscopy, and inspection of the gullet, stomach, and rectum. But in ordinary parlance, the word signifies inspection of the urethra only; special terms being used when inspection of other parts is meant.

INTRODUCTION.—An internal surface may be illuminated by letting light, such as daylight, fall through a straight tube (*direct illumination*); or by rays collected and thrown by mirrors placed conveniently through a tube on to the surface to be examined, and reflected directly to the eye of the observer, or through lenses set at suitable angles (*reflected illumination*); or, lastly, by light generated within the body and reflected to the eye of the observer (*internal illumination*). This last method, in which the electric lamp was placed at the inner end of the tube, and its light thrown directly on to the exposed part, has been abandoned for examining the urethra, on account of the difficulty in shielding that canal from the heat of the glow-lamp; though it is still the mode of illuminating the bladder or other cavities, the walls of which are not in contact with the instrument.

The present mode of examining the urethra and other surfaces is the outcome of the work of many experimenters, the earliest of whom was probably Bozzini (1807), followed by Segalas in 1826. In 1840-46, Avery of London devised the tubes which are still in general use. But the methods of illumination now employed, by gas or electricity, are far superior to those obtainable in Avery's time. Desormeaux improved Avery's

method of illumination, and this was further bettered by Cruise. Still, the apparatus remained too cumbrous for easy use until Grünfeld simplified the application of illumination between 1875 and 1880, and Leiter between 1880 and 1887 perfected the electric method by reflecting light from a glow-lamp along the tubes on to the exposed surfaces. About this time Grünfeld, Dittel, and others, employing these more manageable instruments, were able to describe methodically the appearances of the normal urethra in its several parts, and also many of the changes caused by disease.

APPARATUS.—The apparatus may be arranged in three varieties: in Desormeaux' and Leiter's the lamp and tube are fixed together; in a second, the light is distinct, but the reflectors and lenses are fixed to the tube; in a third, the light and reflector, a concave mirror fastened to the forehead or held in the hand, are both separate from the tube.

The best apparatus is that of Leiter, where the light of an Edison's glow-lamp of 0.5 to 1 ampère is affixed below the outer end of the tube, and its rays reflected through the tube on to the exposed portion of the urethra and back again to the eye of the observer. It comprises a set of straight silver tubes five inches long and of internal diameter ranging between 18 and 26 millimètres. Their inner ends are cut off either transversely or obliquely, and the outer ends have a wide mouth and flange, on to which the funnel and mirror may be fitted. Each tube has a vulcanite plug with a smooth or rounded end that projects beyond the tube, to facilitate its passage along the urethra. The interior is blackened to prevent confusion by reflection from its sides. Dr. William K. Otis, of New York, has contrived curved tubes which can be passed along the urethra to the posterior portion with ease; but curved tubes require a reflector at the end, and the one supplied with the tubes is too clumsy to be of much service. Grünfeld has improved the windowed tubes of Avery—that is, tubes with some part of the side or the end closed by a piece of glass—and for some purposes these windowed tubes are more useful than the open ones. In addition to tubes, lamps, and mirrors, small mops of cotton wool are needed to wipe the mucus, pus, and blood from the displayed surfaces, so that the cleaned and dried membrane may be viewed. For the treatment of the various affections, additional armamenta are strong astringent or caustic solutions, hæmostatics, such as hamamelis, iron, or tannin, and pencils of cupric sulphate or of lunar caustic. To them may be added small electric cauteries, probes, forceps, snares, knives, scissors, curettes, and tubes for insufflation of astringent powders. Grünfeld has also contrived to place outside his endoscopic tube another fine one, through which he can

inject drops of astringent solutions on to inflamed patches.

Batteries of various make are used: that for illumination should have a power of eight to twelve volts; that for cautery, of twenty to thirty volts. Carbolic oil (1 in 16) or glycerine for lubricating the tubes is also needful.

APPLICATION.—When inspecting the urethra it is convenient to divide the canal into two portions—that before the triangular ligament being the anterior, that behind it the posterior. Not infrequently the inflammation set up by gonorrhœa is confined to the anterior portion; while, on the other hand, in gleet of long standing the posterior part may be alone affected, when the anterior section is quite clear of disease.

In the anterior portion are the meatus and the fossa navicularis, the spongy and bulbous parts, into which, with a forward direction, open the ducts of mucous glands and those of Cowper's glands. In the posterior are the verumontanum, the sinus pularis, and the openings of the spermatic ducts and of those of the prostate itself.

Before examining the urethra, it is advisable to pass along the canal a sound or bougie slightly larger than the inspecting tube, in order to be sure that no constriction exists which would prevent the passage of the tube, and also to familiarise the urethra with the presence of instruments. It is well also to refrain from introducing the tube into the posterior portion until that part has become accustomed to instruments by the repeated passage of bougies or sounds. The calibre of the tube should not be large enough to stretch the urethra; if it is, the walls are more or less blanched, and the operation is apt to give pain. These drawbacks avoided, the larger the tube the more easy the examination.

*Examination of the anterior portion of the urethra.*—The best position is the half-recumbent one on a high couch, with the knees bent and the legs hanging over the edge. The observer seats himself on a low stool opposite his patient, his eyes about level with the urethra. If the patient be well accustomed to manipulation he may stand upright on a stool against a wall, to bring his pelvis level with the eyes of the observer sitting before him. All being ready, the operator introduces the tube. If the meatus be much contracted, either congenitally or by fibrous bands after inflammation, it is well to divide the tight bands by the touch of a probe-pointed bistoury, after rendering the part insensible with cocaine. A No. 24 or 26 tube, with its plug, is then slowly passed along the passage until the bulb is reached. The plug is then withdrawn, and the area of the urethra exposed at the end of the tube is well mopped and dried, and the light adjusted. If the urethra is healthy and not scarred or

blanched by previous inflammation, the part now seen is of a delicate rose-pink or purplish pink hue, faintly striated with longitudinal lines. The most distinct streaks or furrows are in the floor at each end of the transversely disposed lumen. Faintly marked crimson papillæ are visible in the anterior portion, but are lost near to the navicular fossa. As the tube is slowly withdrawn, the urethra collapses closely behind it evenly on all sides. The lumen or central figure is an even transverse line or slightly oval figure of symmetrical thickness. The orifice of a lacuna Morgagni is indicated by a little dark dot; though these lacunæ may be difficult to distinguish unless sought for in the way to be described presently. When inflamed, ulcerated, or indurated, these openings are easily distinguished. As the tube continues to retreat at about three inches from the meatus, the colour of the mucous membrane grows paler in many persons, to become again dull pink or bluish pink at the sinus navicularis. Here, also, the lumen changes from a transverse position to a vertical one, being oval or triangular in form. In the roof of the urethra it is not difficult to detect in this fossa the mouths of two or three or more ducts of muciparous glands, and the wall of the passage is not so evenly resilient as it is more posteriorly. To find the lacunæ Morgagni in a healthy urethra, it is often necessary to slightly divert the tube from the axis of the urethra to cause the wall to bulge slightly into the open end of the tube. By this, a larger area of the wall is brightly illuminated. If a lacuna be within the illuminated area, it is distinguished by a dark dot due to want of reflexion, because the floor of the lacuna is lower than the general surface. So, also, the position of a lacuna is revealed during slow retraction of the tube by the sudden appearance of a fine furrow or seam in the wall, radiating from the lumen and made more distinct by the greater brilliancy of the light reflected from each side of the furrow. Very shortly the seeming furrow or line disappears as the tube passes from it. The openings of the ducts of Cowper can be more easily found, as they have a more constant position in the urethra. They open into the bulbous portion, where they appear as two dark dots, side by side, soon after the lumen has assumed its transverse linear form.

*Examination of the posterior portion of the urethra.*—In this portion, proceeding from behind forwards, are to be seen the os internum urethræ, the walls of the prostatic portion, the verumontanum, the openings of the prostatic ducts and of the ejaculatory ducts, and the membranous portion of the urethra.

The ordinary straight tube with open end, five inches long and of the calibre suitable for the anterior part of the urethra, is the best to use for this purpose. A special move-

ment is required to pass the tube through the triangular ligament without exciting contraction of the voluntary muscles which encompass that portion of the canal, and which resist the passage of the tube, and thereby hurt the patient.

In introducing the tube, the end rounded by the plug should be pressed gently down the urethra so that it follows the floor, not the roof, until it reaches the triangular ligament. There, while steady pressure is maintained, the hand is lowered deeply between the thighs until the deeper end rises and slips on in spite of the slight resistance always made to its onward passage. When resistance ceases, the tube is pushed backwards for another inch or so, and held steadily while the plug is withdrawn and the light adjusted. If this is done slowly, the pain, should the patient feel any, ceases as soon as the instrument stops moving. It is often well to get the patient to hold the tube himself during the adjustment of the lamp, as he is less likely than the operator to move it inadvertently. But a steady, gentle pressure must be kept on the tube while it is in this region, or it will be ejected by the muscles of the urethra, and will be suddenly thrust forth into the bulbous portion. The part being well wiped and the light thrown on, this portion of the urethra will appear funnel-shaped, and of full rosy hue or pale purple, or yellowish white if there have been inflammation or induration of the prostatic portion at some time before. At the *os internum* the lumen is long, horizontal, and marked at each end by two radiating creases. If now the tube be pushed back a little, it is quickly filled by urine, and a misty yellow light is all that is visible. This accident is easily avoided by practice; but if it happens, the tube must be withdrawn a little, and its outer end depressed that the urine may flow out. This done, the mops dry up the remaining moisture, and the inspection may begin. Besides the conditions already mentioned, in some cases fine longitudinal striæ or creases are seen to radiate pretty uniformly from the centre. These are probably rows of fine papillæ along shallow folds of the membrane. The tube is slowly withdrawn, bit by bit; and, as it recedes, here and there a dot or depression may be noted placed in no definite position on the wall. These dots are orifices of ducts of the prostate. Gradually, while the end of the tube recedes, there rises into view a saddle-shaped eminence like an inverted U, with the top at the highest point of the exposed surface, around which the walls closely conform. This is the *verumontanum*, or *caput gallinaginis*. It has usually a paler colour than the wall, but is never white unless diseased. Presently, when the saddle-shaped eminence is at the highest, two small red fossæ or furrows can often be seen on either side of the central ridge, and

equidistant from it. These are the outlets of the ejaculatory ducts; and usually near them, but more outward, some more dots appear, signifying the orifices of the prostatic ducts. Occasionally, if the tube be kept still or pressed firmly against the floor, a little whitish-grey bead forms on one of the symmetrically placed hollows. This is semen, and, if wiped away and put under the microscope, is seen to contain the characteristic spermatozooids. Not infrequently the mouths of the ejaculatory ducts are not found by this method. They may then be generally detected by pushing the tube back a little and pressing it up against the roof to allow the floor to rise more. If the outer end of the tube be now raised, the light shines more strongly on the *veru*, and as the tube recedes the furrows generally become distinct. When they are clearly seen, a fine whalebone bougie or silver probe may, it is said, sometimes be coaxed into them for a short distance. On still further withdrawing the tube the saddle-shaped eminence widens at its base, the lumen loses the shape of an inverted U, and grows circular or oval, with the long diameter vertical. The walls also rise up into the area before the tube, and have a paler hue, making a broad pinkish ring inside the tube. When this appears, the membranous portion has been reached. If there have been bygone inflammation of the part, the ridge of the *veru*, instead of being like an inverted U, is like an inverted V, and of much lighter colour, even white, from induration and wasting. Small veins, showing as dark sinuous lines, are not uncommonly seen in the prostatic portion, and, but less frequently, in the anterior portion also.

BERKELEY HILL.

**ENEMA** (*ἐνίημι*, I inject).—SYNON.: Lave-ment; Clyster; Fr. *Clystère*; *Lavement*; Ger. *Klystier*.

**DEFINITION.**—An enema is a liquid injected by means of a suitable instrument into or through the rectum.

**INSTRUMENTS.**—Various instruments are used for the administration of enemata: 1. A simple elastic bottle with ivory or gum-elastic pipe, which has superseded the old bladder and pipe. 2. An indiarubber bottle with flexible tube at either end and double action, as in Higginson's instrument. 3. An ordinary piston syringe, worked by the hand, which is either simple, or provided with a double action, so as to supply a continuous stream. 4. A French instrument, known as the *irrigateur*, worked by a spring. 5. The hydraulic enema, which consists of a piece of indiarubber tubing about six feet long, furnished with an ordinary ivory rectum-pipe at the one end, and a metal cone, or a screw nozzle, at the other. The tube, being filled with the injection, has one end placed in the containing reservoir, or is connected

by the screw; while the pipe at the other end is introduced into the bowel. The vessel supplying the injection being placed on an elevation, the liquid gravitates into the bowel, filling the large intestine. When it is desirable to inject a large quantity the patient should lie first on the left side, then on the back, and lastly on the right side, to promote the filling of the intestine. In all cases care should be taken to prevent the injection of air into the bowel, and also to ascertain that the nozzle of the injecting pipe is free in the rectum, not in contact with the sphincter, not thrust against the sacrum or into a hard fecal mass. The process of injection must be carried on slowly, with occasional pauses, otherwise premature contraction of the bowel with expulsion of the enema will result.

**VARIETIES AND USES.**—The chief varieties and uses of enemata are as follows:—

1. **Anthelmintic Enemata.**—To cure thread-worms injections of salt and water, or lime-water, or from two to four drachms of spirit of turpentine diffused by yolk of egg in four ounces of water, are serviceable. The enema of aloes or of asafœtida may also be employed in the small quantity just named.

2. **Antispasmodic Enemata.**—Puerperal convulsions have been relieved by the injection of half a drachm or more of chloral hydrate. Injections of asafœtida or of rue are also given. Injections of warm water with two or three fluid-drachms of sulphuric ether have sometimes relieved spasmodic invagination of the bowels. When the intestine is tympanitic and distended, the enema terebinthinæ, or enema asafœtidæ, will act well as a stimulant and carminative.

3. **Astringent Enemata.**—These are used either to check diarrhœa, to arrest hæmorrhage, or to remedy ulceration and mucous discharges. For the first of these purposes the enema opii is valuable. In cases of hæmorrhage from the bowels, as well as from the womb, injections of ice-cold water are frequently used. Ulceration with mucous discharge is often successfully treated with enemata of nitrate of silver (five grains to one pint of distilled water), of sulphate of zinc or alum (one or two grains to the ounce of water), or of sulphate of copper (one grain to the ounce of water).

4. **Emollient Enemata.**—Demulcents, such as decoctions of starch, linseed, or barley, or pure linseed oil, are at times used with the object of imparting nourishment to the system, and of soothing an irritable mucous membrane.

In dysentery, from four to six pints of warm water, or of milk and water, have been injected as a form of internal fomentation.

5. **Nutrient Enemata.**—In cases of exhaustion, enemata of peptonised milk, beef-tea and eggs beaten up are used. About

four or six ounces should be given at once by means of an indiarubber bottle with an elastic-gum rectum tube. When properly given, they will remain and be absorbed. Should the rectum become irritable, the irritability may be often lessened by adding a few drops of laudanum to each enema. A solution of defibrinated blood, in its recent or dried form, has been recommended as a material for nutrient enemata (see paper by Dr. Sansom on Supplementary Alimentation, *Lancet*, 1881, vol. i. p. 288). The digestion and assimilation of nutrient enemata may be facilitated by the addition of preparations of pancreatin and pepsin. See PEPTONISED FOOD.

Injections of brandy and water, or beef-tea and brandy, have been given with benefit in prostration from uterine hæmorrhage or other causes.

6. **Sedative Enemata.**—These are often employed in painful affections of the rectum and bladder. The enema opii is very useful. In spasm of the bowels and in hernia the enema tabaci has been resorted to, but it must be used with caution, as it may produce faintness and collapse.

7. **Purgative Enemata.**—These are used to overcome constipation. For this purpose—in the case of an adult—from one to two pints of fluid must be slowly pumped into the bowel. When the process is conducted gradually, stopping occasionally and making pressure on the anus if the injection threaten to come away, as much as four or five pints can be got into the bowel. The injection should be retained as long as possible, as thus a complete evacuation is ensured. As a general rule, about a pint of liquid is enough for an adult; for an infant an ounce; for a child of four years, four to six ounces.

**Composition.**—Soap and water, gruel with olive-oil, castor-oil, and sometimes oil alone, may be used. The enema magnesii sulphatis is an efficient purgative. Enema aloes is also valuable.

Glycerine is now used in cases of defective action of the bowels. From one to two drachms are injected by a suitable syringe into the rectum, and in from five to thirty minutes action of the bowels will follow. There is often more or less straining, with expulsion of flatus; and, if the quantity used be too large, violent and spasmodic action may result.

Glycerine suppositories have been added to the Pharmacopœia. Their action is attended with less spasm than is that of the fluid injection. The glycerine acts as a stimulant and irritant to the rectum; for while some amount of burning is felt, a thermometer shows increased temperature in the rectum. Where the accumulation lies high up in the intestine, glycerine injection has little or no effect in causing its expulsion.

In cases of intestinal obstruction the introduction of a large volume of soap and water—with oil, perhaps, added—by means of the gravitation-tube, may be had recourse to with advantage. Obstruction due to impacted feces generally yields to this method of treatment, especially if assisted by judicious massage of the abdomen.

The gradual injection of air by means of a bellows and rubber tube, or a Lund's insufflator, into the large intestine has proved a successful method of treating intussusception of the bowel in young children, especially in cases where the intussusception can be easily felt by the rectum, and where enemata are at once returned. *See* **INTESTINAL OBSTRUCTION**.

The frequent use of very large injections is undesirable, lest undue distension result, with weakness and loss of tonicity in the bowel. The habitual use of injections washes away the mucus designed to lubricate the bowel.

JOHN C. THOROWGOOD.

**ENGADINE, UPPER; in Switzerland.**—A bracing mountain climate. Elevation of valley 5,000 to 6,000 feet. Season, June to September. Some places are also open during the winter. *See* **CLIMATE**, Treatment of Disease by.

**ENGHIEN, in France.**—Sulphur waters. *See* **MINERAL WATERS**.

**ENGLISH CHOLERA.**—A synonym for simple cholera or choleraic diarrhœa. *See* **CHOLERAIC DIARRHŒA**.

**ENGORGEMENT.**—Overloading of the vessels, or of the heart, with blood. A synonym for congestion. *See* **CIRCULATION**, Disorders of.

**ENTERALGIA** (*έντερον*, the intestine; and *άλγος*, pain).—**SYNON.**: Enterodynia; *Neuralgia mesenterica vel mesaraiica*; Colic.

The terms enteralgia and colic—generally regarded as synonymous—include all forms and degrees of paroxysmal intestinal pain in cases where there is no febrile disturbance. Enteralgia, implying more especially the neuralgic nature of the sensori-motor disturbance, is sometimes preferred, as by those who hold that colic proper—of which lead-colic is a typical example, as distinguished from symptomatic colicky pains—is a visceral neuralgia. It is likewise frequently applied to colic occurring in the neurotic—in whom there is not uncommonly a record of other forms of neuralgia in the individual or family history—the asthenic, the anæmic, or the gouty, even when there is a local exciting cause, such as flatus, retained feces, &c.; and to conditions in which pain predominates over spasm. The clinical features of enteralgia are, however, as a rule, indistinguishable from those of colic. A similar local disturbance—pain either sudden and sharp

or gradual and dull, either about the umbilicus or in the right iliac region—according to its intensity, is reflected by the nerves to the heart and the peripheral arteries. The action of the former becomes slow and feeble, and the latter contract; hence arising the small, infrequent, tense pulse, the cool pale skin, and the other signs of collapse which mark the distant effects of colic. And, as in this disorder, the termination of the attack may be sudden, perhaps following the expulsion of flatus or feces—a free perspiration, a copious flow of pale urine, the menstrual or lochial or other discharge, or a fit of the gout. As a rule, the more severe the paroxysm the shorter will be its duration. The exciting cause is not uncommonly a chill (wet feet, &c.), or mental over-strain and worry. Persistent enteralgia is now and then indicative of spinal disease, such as caries.

**TREATMENT.**—The main indications in the treatment of enteralgia are to endeavour to remove any cause of the pain: to administer opium or belladonna by the mouth or rectum, or subcutaneous morphine, and to apply hot fomentations, with laudanum and turpentine, for the relief of the suffering (*see* **COLIC**, **INTESTINAL**); and, during the intervals between the seizures, to restore the nutrition and tone of the nervous system, and improve the general health. Among medicines, courses of the hypophosphites, belladonna, quinine, and arsenic may be found most useful.

GEORGE OLIVER.

**ENTERIC FEVER.**—A synonym for typhoid fever. *See* **TYPHOID FEVER**.

**ENTERITIS** (*έντερον*, the bowel).—Inflammation of the intestines. *See* **INTESTINES**, Diseases of.

**ENTEROCELE** (*έντερον*, the bowel; and *κήλη*, a tumour).—A hernia containing a portion of bowel. *See* **HERNIA**.

**ENTOPHYTE** (*έντός*, within; and *φυτόν*, a plant).—A plant parasitic in any part of the body. *Entophytic diseases* are diseases that are supposed to depend upon the growth of such plants, as, for example, fungus-foot. *See* **FUNGUS-DISEASE OF INDIA**.

**ENTOZOA** (*έντός*, within; and *ζῶον*, an animal).

Man, in common with other animals, vertebrate and invertebrate, is liable to entertain various forms of entozoa. In comparison with other vertebrates, even with members of his own order, Primates, the number known to infest man is singularly small. This is attributable in a large measure to the fact that his food is submitted to the process of cooking. The various entozoa found in the human subject are truly parasitic, and not examples of commensalism. A parasite inhabits a living organism, and

obtains nourishment from its body. In *commensalism* creatures live within the bodies of larger animals, like parasites, but share its food, or live upon the refuse of its body instead of the juices and tissues of the host. The more important entozoa found in man are:—

- I. *Cestoda*, Tapeworms.
- II. *Trematoda*, Flukes.
- III. *Nematoda*, Round-worms.
- IV. *Gregarinidæ*, Psorosperms.
- V. *Rhizopoda*, Amœba coli.

I. *Cestoda*, or Tapeworms (κεστός, a girdle).—Fr. *Cestoïdes*, *Ténia*; Ger. *Bandwurm*.

Varieties:—

- a. *Tænia solium*.
- b. *Tænia mediocanellata* vel *saginata*.
- c. *Tænia bothriocephalus* *latus*.
- d. *Tænia cucumerina* vel *elliptica*.
- e. *Tænia nana*.
- f. *Tænia echinococcus*.

a. *Tænia solium*.—This worm when fully developed may attain a length of 2 to 3 feet. The vertex or head, about the size of a small pinhead, is furnished with four suckers, a rostellum, and twenty-six hooklets (fig. 34). A narrow neck succeeds the head, and at a short distance the segments begin to be visible. At first their breadth exceeds their length; but farther from the head they lengthen, until the mature segments are reached. These average 12 mm. in length and 5 mm. in width.

Each mature segment contains male and female generative organs. The genital openings are at the sides of the segments near the middle: the ovary presents seven to ten branches, each ending in a dendritic manner (fig. 36).

*T. solium* inhabits the small intestine of man, and is acquired by eating pork. Infection takes place in the following manner: The eggs, either free or contained in the segments (proglottides), are evacuated from the host, and are conveyed either by means of food or drinking-water into the body of a pig or other animal. When the eggs reach the stomach of the pig the capsule is dissolved, and the liberated embryo makes its way into the wall of the intestines or is carried by the blood-current into other parts of the body. The young tapeworm, when it emerges from the egg, possesses six hooklets, and is known as the 'six-hooked embryo.' After settling in the tissues it becomes metamorphosed, and is now furnished with a head and becomes enveloped by a membrane. In this condition it is known as a 'measle' or *Cysticercus cellulosa* (κύστις, a bladder; and κέρκος, a tail) (fig. 32). Pork containing the cysticercus is said to be 'measled.' The cysticerci are destroyed by thorough cooking, either by boiling or the more satisfactory process of roasting. When a cysticercus is introduced into the intestine,

the head (scolex) fixes itself into the mucous membrane, the cyst-membrane is dissolved, a chain of segments or proglottides develop, and a tapeworm is the result.

The cysticercus occurs also in man, and is probably due to the introduction of the eggs of *T. solium* into the stomach. Cysticerci have been found in the aqueous and vitreous chambers of the eye, in the subcutaneous tissue, and in muscles. When encysted they retain their vitality for many years. The presence of these small bodies excites local irritation, inducing inflammatory thickening. In muscles and intermuscular tissue they occasionally cause swellings resembling tumours. In the brain, when numerous, they induce fatal results. A few may exist in the cortex of the cerebrum without producing any obvious effect, but in the neighbourhood of the medulla two cysticerci have been known to cause death. In the eye cysticerci have been detected by means of the ophthalmoscope. In this situation they present a striking and characteristic appearance.

b. *Tænia mediocanellata* vel *saginata*.—This tapeworm differs from *T. solium* in several important particulars. When fully developed it may attain a length of 4 feet. The segments are thicker and wider than in *T. solium*; it has no rostellum or hooklets, but four suckers or proboscides and

FIG. 32.—*Cysticercus (telæ) cellulosa*, removed from the human eye by Mackenzie.  $\times 5$  diam. After Allen Thomson.

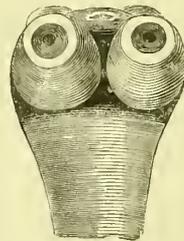

FIG. 33.—Unarmed Head of *Tænia mediocanellata*.  $\times 10$  diam. After G. Fritsch.

FIG. 34.—Armed Head of *Tænia solium*.  $\times 10$  diam. After G. Fritsch.

a median canal (fig. 33). The mature segments have a larger number of uterine diverticula, and they do not end dendritically (fig. 35). The cysticercus of this tapeworm infests the muscles of oxen. The tapeworm itself is acquired by man in consequence of eating underdone beef. In the accompanying sketches the heads and proglottides of *Tænia solium* and *Tænia mediocanellata* are arranged side by side for comparison.

c. *Tænia bothriocephalus latus*.—This is the largest tapeworm infesting man; when mature it attains a length of 5 to 8 feet, and contains two, three, and even four

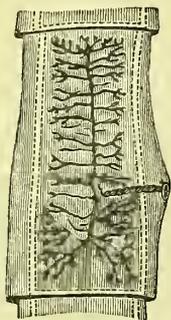

Fig. 35.—Proglottis of *Tænia mediocanellata*.  $\times 1\frac{1}{2}$  diam. After G. Fritsch.

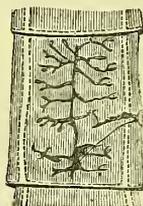

Fig. 36.—Proglottis of *Tænia solium*.  $\times 1\frac{1}{2}$  diam. After G. Fritsch.

thousand segments. The uterus has the form of a coiled ribbon, and the genital opening is near the middle of the ventral surface.

This worm lives in the small intestine, and is met with mainly in Switzerland and north-eastern Europe. It has been reported as occurring in Ireland.

It has long been suspected that fish were the intermediate host of this cestode, and Braun has demonstrated its occurrence in the larval stage in the muscles and viscera of pike, trout, and turbot.

d. *Tænia cucumerina* vel *elliptica*.—This is a small tapeworm, common in cats and dogs, rarely found in man. It has a rostellum and about sixty hooklets arranged in four irregular rows. The intermediate host is the dog-louse, *Trichodectes canis*. This fact explains the large number of *tænia* found in dogs not cleanly kept. The lice worry the dog, and it licks the irritated parts, and thus takes the lice with the cysticerci into the alimentary canal. Stroking dogs, or receiving their lingual caresses, is probably the means by which man is infected. It is noteworthy that children have furnished nearly all the specimens of this worm which have been reported in the human subject.

e. *Tænia nana*.—This is a small tapeworm. The head has four suckers, a rostellum, and circlet of twenty-two to twenty-eight hooklets. Bilharz found it in great numbers in the duodenum of a boy in Egypt. It is very rarely entertained in the alimentary canal of man.

**SYMPTOMS.**—The presence of tapeworms is indicated by a great variety of symptoms. Among the more important may be mentioned interference with the digestive process, irritability, and restlessness at night. Anæmia, headache, and vertigo are not uncommon. Irritation about the anus is sometimes a source of annoyance. Reflex pheno-

mena, such as chorea, convulsions, or epileptiform seizures, insanity, mania, squint, and other untoward conditions, have been known to coincide with the presence of tapeworms in the alimentary canal, and to disappear when the worms have been expelled. Many other grave phenomena have been attributed to their presence. It is equally true that hundreds of individuals entertain tapeworms and suffer no inconvenience in consequence, nay, even are unaware of their guests until apprised of the fact by the appearance of two or three feet of cestode segments passed *per anum*.

**TREATMENT.**—Many drugs have been recommended, such as turpentine, kousso, kamala, areca-nut, and other anthelmintic remedies. The late Dr. Cobbold, after a long experience, came to the conclusion that the liquid extract of male fern is the most reliable drug. The patient, if adult, should take a dose of castor-oil at night, a drachm of extract early next morning on an empty stomach, to be followed in three hours by a small dose of castor-oil. The fragments of worms should be examined in order to ascertain if the head be expelled.

f. *Tænia echinococcus* and *Hydatidis (vâdaris)*, a drop of water).—Fr. *Hydatide*; Ger. *Blasenwurm*.—*Tænia echinococcus* is especially interesting because its larval stages occur in man under the name of hydatid cysts.

The mature *tænia* inhabits the intestine of dogs, jackals, and wolves. It is about 4 mm. in length, and consists of only four segments, of which the terminal one alone is mature. Its head has four suckers, a rostellum, and two rows of hooklets, varying in number from fourteen to twenty-five in each row.

The eggs of this worm are introduced into the alimentary canal with the food, but more commonly with drinking-water. The six-hooked embryo, emerging from the egg, makes its way into surrounding tissues, and is frequently carried along by the blood-current in the veins as an embolus, to find a resting-place in lungs, kidney, liver, omentum, or brain, and becomes gradually transformed into an hydatid cyst.

Fig. 37.—*Tænia echinococcus*.

For the history of the early stages of these cysts we are indebted to the zeal and industry of Leuckart. At first they are small white dots, with thick, homogeneous, transparent capsules, with concentric lamination, enclosing coarsely granular contents (fig. 38). After the cyst has been growing five months, and has attained a diameter of half an inch,

echinococcus-heads begin to bud from its walls. Each of these heads, when fully formed, is about 0.3 mm. in length when fully distended, and represents the head and neck of an adult echinococcus (fig. 39). Each head is furnished with four suckers and an armed rostellum, the hooklets of which are

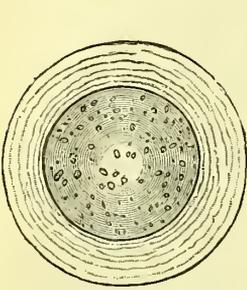

FIG. 38.—Hydatid of four weeks' growth, showing ectocyst and endocyst.  $\times 60$ . After Leuckart.

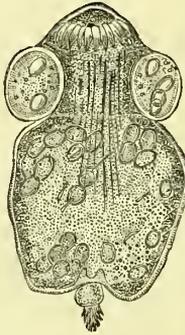

FIG. 39.—The so-called *Echinococcus* head, showing hooks, suckers, cilia, and corpuscles.  $\times 250$  diam. After Huxley.

very small. Numerous calcareous particles are lodged in its parenchyma. The rostellum with its hooks and suckers can be retracted and extended. In examining such specimens under the microscope it is usual to find them in the inverted or retracted condition shown in fig. 40. The heads or scolices are formed within brood-capsules, and Leuckart emphatically states that they are throughout life

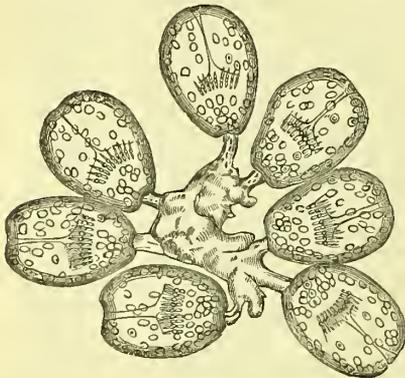

FIG. 40.—Group of *Echinococci*, with their hook-crowns inverted.  $\times 180$  diam. After Busk.

directly continuous with each other by means of the parenchyma of the main cyst, and cannot roam about the cavity and retain their vitality. The walls of hydatids consist of two layers, an outer or cuticular and an inner layer or parenchyma. The cuticular layer is highly elastic and curls up when divided; the parenchyma consists of granular matter, cells, and muscle-fibre. The brood-

capsules are developed from the parenchyma; each brood-capsule, like the parent-cyst, has two layers, an *outer* parenchymatous and an *inner* cuticular, thus reversing the conditions of the mother-cyst. Leuckart maintains that the scolices bud from the outer wall of the capsule; but when fully developed invaginate, so that what was formerly the internal cuticular surface of the head now becomes external. This view requires confirmation. The mother-cyst grows larger as fresh brood-capsules are formed. Every echinococcus cyst does not develop brood-capsules, and may attain a large size yet remain sterile. The presence of the cyst irritates the surrounding structures, and leads to the formation of a spurious capsule of fibrous tissue, sometimes of great thickness and usually very vascular. The brood-capsules, with their contained scolices, occur in clusters; each capsule is of the size of a No. 5 shot. Occasionally the capsules become much larger and form internal daughter-cysts attaining in some specimens the size of a Tangerine orange. Such daughter-cysts may develop cysts of their own, or granddaughter-cysts. When endogenous daughter-cysts are present, the mother-cyst is, as a rule, of very large size, and contains as many as two or three thousand daughter-cysts varying in size from a pea to an orange. Occasionally, we find in echinococcus cysts occurring in cattle, that daughter-cysts are formed from the cuticle and protrude beyond the *external* wall of the parent-cyst, and form brood-capsules. A few examples of this condition have been reported in the human subject.

*Echinococcus multilocularis* is a variety of hydatid, which has been described as affecting the liver. It forms a hard tumour made up of alveoli, separated by fibrous tissue. The alveoli are filled with gelatinous transparent material, stained at times with bile. Such specimens were formerly described as colloid cancer of the liver, until Virchow pointed out that they were composed of echinococcus cysts, and occasionally contained scolices. Nearly all the reported cases have occurred in South Germany and Switzerland. The true nature of this form requires elucidation. The recognition of *E. multilocularis* is rendered more difficult by the circumstance that they sometimes ulcerate. This condition may easily be confounded with actinomycosis of the liver.

**ANATOMICAL CHARACTERS IN MAN.**—The human body frequently contains echinococcus cysts; there is scarcely an organ in which it has not been found, even in the medullary cavities of bones. Like the *cysticercus cellulosa*, the embryo of *T. echinococcus* has its favourite situations: the former selects chiefly the intermuscular connective tissue and brain, the latter selects mainly the viscera, especially the liver. The liability of organs to entertain hydatids may be in-

ferred from Neisser's tables as quoted by Leuckart. They are based upon an analysis of 986 cases : Liver, 451; lungs and pleura, 84; kidney, 80; brain, 68; muscles, dermis, and orbit, 72; spinal cord, 13; pelvis, 36; circulatory organs, 29; spleen and bones, 28, and so on. This table is only useful as showing the greater liability of viscera to harbour this parasite. In the bones, eye, orbit, mamma, thyroid body, and heart it is of extremely rare occurrence.

It is strange that, though the liver is such a favourite viscus for hydatids, it is rare to find more than one cyst present in this organ at the same time in the human subject; yet in swine they are frequently multiple. In man, one large cyst may be lodged in the liver, and twenty, thirty, or even a hundred occupy the omentum, mesentery, &c. This condition is, however, very uncommon.

**SYMPTOMS.**—The danger caused by these cysts arises mainly from the mechanical pressure they exercise on surrounding parts. Thus, in the brain or heart, a cyst the size of a hazel-nut gives rise to serious disturbance, but one as large as a man's head is often tolerated in the liver or pelvis. These cysts are often found *post mortem* when their presence had never been suspected during life, although they attained goodly proportions. The parasite may die early in its career, and the cyst-wall calcify; hydatid membranes seem very prone to this change, the calcareous matter resembling very old dried mortar. Hydatid cysts cause death in a variety of ways. In the brain they simulate cerebral tumour, and induce death early, especially when growing near the bulb. In the spinal cord they produce paraplegia. In the liver they may be accidentally ruptured, and cause death in a few hours from shock and hæmorrhage combined, or, later, from peritonitis. In some instances, after injury or meddlesome tapping, suppuration takes place with septic troubles, which the formation of pus entails. Liver cysts may perforate the diaphragm, and rupture into the pleura, or communicate with the lung and its bronchi. Occasionally they open into stomach or bowel, the scolices being discharged *per anum*. They have been known to rupture into the bile-passages, the transit of the scolices causing biliary colic. Among the rarer sites of rupture may be mentioned the pericardium, vena cava inferior, or through the parietes of abdomen or thorax.

In the lung pressure upon the air-cells or bronchi may cause gangrene and other troubles which follow bronchial obstruction. Hydatid cysts of the thyroid body are very rare; they usually rupture into the trachea and cause death by suffocation.

**DIAGNOSIS.**—The diagnosis of hydatid cysts, in organs other than the liver, is attended with very great difficulty; and as these cysts frequently appear at *post-mortem* examina-

tions and astonish the physicians, so are they one of the most fertile sources of surprise to enterprising surgeons. In the liver a hydatid cyst may be suspected when a tumour can be made out unaccompanied by pain, cachexia, high temperature, or wasting.

The conditions most likely to be confounded with hydatid cysts in the liver are abscess, distended gall-bladder, effusion in the right pleura, aneurysm of the abdominal aorta or hepatic artery, cancer of the liver, renal cysts, dilated stomach, pancreatic cyst, ovarian tumours, and dropsy due to closure of Winslow's foramen. See LIVER, Hydatid Disease of.

It is not wise to rely on the fact that the patient has lived among dogs or in a pastoral country. Individuals who have never kept or lived with dogs often develop hydatids.

When an abdominal or thoracic tumour is suspected to be a hydatid cyst (these are the situations in which physicians are most frequently called upon to diagnose them), the nature of the swelling should be ascertained by puncturing it with a trocar, and drawing off some of the fluid. The characters which determine its echinococcus nature are the following:—

The fluid is limpid, colourless (occasionally bile-stained when growing in the liver), and in specific gravity varies from 1009 to 1015. Free from albumen, it contains chloride of sodium, and is said to furnish traces of succinic acid, leucin and tyrosin. The three last are present in quantities too small to be of any clinical value. The most positive signs are the presence of brood-capsules, scolices, hooklets, or the gelatinous, trembling, laminated membrane which forms the true wall of the cyst, and is in itself absolutely peculiar to hydatids.

It must also be remembered that hydatid cysts are occasionally sterile—that is, they contain no brood-capsules and furnish no hooklets. Such cysts frequently attain a large size, and seem to occur most frequently in the pelvis; they are as a rule mistaken for other forms of cysts.

**TREATMENT.**—The treatment of hydatid cysts is entirely surgical. In such an organ as the liver the cyst should be freely opened, and its edges stitched to the sides of the incision and drained. The walls collapse, the cyst-membrane comes away during the operation, or is subsequently discharged piecemeal. The cavity then slowly granulates.

When hydatids are lodged in the omentum they are easily removed by abdominal section. When deeply placed in the pelvis they may be situated between the bladder and the rectum in the male, or burrow between the layers of the broad ligament in the female. These are better treated by incision and drainage. Hydatid cysts have many times been recorded in the kidney, but it is very unusual for them to exceed the dimensions of

an orange. They exhibit a marked tendency to discharge into the renal pelvis, the vesicles escaping by way of the urethra. Should the cyst attain such proportions as to give rise to a palpable tumour, it should be explored by a lumbar incision, and treated in the way recommended for the liver. Such cysts arising in the kidney have been known to open into the lung, into the stomach, or communicate with the intestine. Intra-thoracic hydatids are best treated on the same surgical lines as empyema. In the subcutaneous tissues and orbit they are rarely diagnosed—indeed, these cysts in such situations can only be suspected; the suspicion is confirmed when the vesicles or portions of membranes escape during removal of the tumour. Intracranial hydatids have in Sydney, Australia, been successfully submitted to surgical procedure. It is certain that no tumour or cyst connected with the brain offers a more favourable prospect to surgeons than a hydatid cyst connected with the cerebral cortex.

**II. Trematoda, or Flukes (τρήμα, a hole).—Fr. Trématodes; Ger. Trematoden; Saugwürmer.**—These forms have only one opening to the digestive cavity.

Varieties:—

- a. *Distoma hepaticum*.
- b. *Distoma lanceolatum*.
- c. *Distoma hæmatobium* vel *Bilharzia hæmatobia*.
- d. *Distoma Ringeri*.—See p. 259.

a., b. The first two are rarely seen, though they are common enough in the biliary passages of sheep and oxen. They are vulgarly known as flukes, and are the cause of the destructive disease known as 'the rot' of sheep. When flukes, with the exception of the *Bilharzia hæmatobia*, occur in man, they occupy the biliary passages, but are usually present in such limited number as to rarely cause any serious disturbance of health.

c. *Bilharzia hæmatobia*, or *Distoma hæmatobium*, unlike other forms of flukes, has the sexes distinct. The male is 12–14 mm. long, and has a flattened body, which, at its posterior part, is rolled into a kind of tube, constituting the gynæcophoric canal. The female is almost cylindrical in form, and 16–19 mm. long, being lodged within the gynæcophoric canal (fig. 41). The mature worms live in the inferior vena cava, portal, splenic, mesenteric, vesical, and hæmorrhoidal veins of men and monkeys. The ova pass into the mucous membrane of the bladder and intestine, probably escaping as a consequence of the rupture of small vessels. Occasionally the ova may be found in the ureter and the pelvis of the kidney. The ova, often present in great numbers, are furnished with either a terminal or a lateral spine. Dr. Zancarol says that ova with a lateral spine occur in the intestine; those with the terminal spine in the mucous membrane of the bladder. The use of this ap-

pendage has not yet been satisfactorily explained (fig. 42).

The *Bilharzia* is common in Egypt, Abyssinia, the Cape, and Natal. The cercaria, as

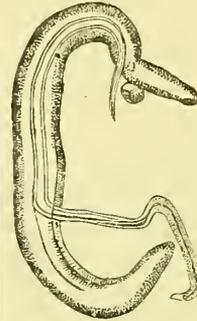

FIG. 41.—*Bilharzia hæmatobia*, male and female sexually combined. Magnified. After Küchenmeister.

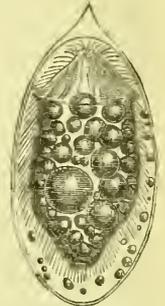

FIG. 42.—Ovum of *Bilharzia hæmatobia* with contained embryo and free sarcodermic granules.  $\times 234$  diam. Original.

the larval forms are termed, abound in rivers and canals, and are especially common in the Nile. When taken into the alimentary canal the cercaria quickly work their way into the mucous membranes, gain access to blood-vessels (veins), and develop into mature flukes.

**SYMPTOMS.**—When lodged in the intestines they give rise to dysentery; in the bladder and ureters, to cystitis, hæmaturia, and vesical calculus. The hæmorrhage caused by their presence in the genito-urinary tract is known as 'endemic hæmaturia.' The eggs, whilst still within their host, may develop ciliated embryos. The disease may be suspected when hæmaturia occurs in persons coming from countries where the *Bilharzia* abounds: the diagnosis is confirmed by finding under the microscope the ova embedded in fragments and shreds of mucous membrane passed with the urine.

**TREATMENT.**—Means must be taken to allay the vesical irritation by such remedies as buchu, uva ursi, hyoscyamus, and the like. No remedy is known that acts as a parasiticide to the *Bilharzia*. It is wise to remove the patient, if possible, from an infected locality. Cure is likely to be protracted, and as yet we are ignorant of the duration of life of the fluke.

**III. Nematoda, or Round-worms (νήμα, a thread).—Fr. Nématoides; Ger. Fadenwürmer.**

Varieties:—

- a. *Ascaris lumbricoides*.
- b. *Oxyuris vermicularis*.
- c. *Trichocephalus dispar*.
- d. *Ankylostoma duodenale*.
- e. *Filaria medinensis*.
- f. *Trichina spiralis*.
- g. *Filaria sanguinis hominis*.

Most of these inhabit the alimentary canal, and when restricted to this region rarely give rise to dangerous symptoms, unless they be very numerous; but they are apt to migrate and invade other organs, and thus give rise to dangerous and often disastrous results.

*a. Ascaris lumbricoides*.—This, the common round or maw-worm, is of cylindrical shape, pointed at each end, and of a light brown colour. The female, as is usual among nematodes, exceeds the male in size. The length of the female varies from 25 to 40 cm. The male is distinguished by the presence of two chitinous spines near the caudal end of the body (fig. 43). This extremity is also bent and hook-like. The spines indicate the male genital orifice. In the female the genital pore is situated near the middle of the body. The ova are very numerous; when mature they possess a double shell surrounded by an albuminous coating, have considerable power of resistance, and are not killed by drying or freezing.

The life-history of the worm is not fully known, and we are ignorant of its intermediate host. Dr. Cobbold was of opinion that it did not require one, but that the eggs develop in water.

This worm lives chiefly in the small intestine, but may wander into the stomach, and even pass up the œsophagus and be discharged through the mouth. An *ascaris* has been known to creep into the bile-duct and cause jaundice. In cases of perforation of the intestine in fatal cases of typhoid fever, these worms have been found lodged in the aperture. We must not conclude from this that the worm caused the perforation; it is more reasonable to believe that when the accident happened the ascaris was passively lodged in the opening during the outward rush of the fluid contents of the bowel. It is possible that

Any foreign body in the intestine is sure to attract their attention and to form a sort of 'worm-trap.' Thus they have been strangled by metallic buttons, hooks and eyes, open-topped thimbles and the like (Cobbold).

**SYMPTOMS.**—It is unusual for an individual to harbour more than two or three round worms, and as a rule they rarely give rise to symptoms. When present in large numbers—a condition of things most common in children—diarrhœa, colic, nausea, vomiting, and convulsions may occur. Children have been known to pass in the course of a few years. one hundred worms, and in one case 510 worms were voided by a child. Generally the passage of a worm by the anus or mouth is the first and only indication of its presence.

**TREATMENT.**—The most reliable drug is santonin, in the form of a powder: for children two to four grains, followed by a saline purge or castor oil; for adults five grains daily; for three days each dose to be followed by castor oil. Among other useful remedies we may mention aloes, scammony, jalap, calomel, kamala, sulphur, and turpentine.

*b. Oxyuris vermicularis*

(*Thread- or Seat-worm*).—The thread-worm is an inhabitant of the colon and adjacent parts of the ileum. The female is usually about 10 mm. and the male 4 mm. long. In addition to its greater size the female has a sharp-pointed tail, whereas in the male it is blunt and furnished with a spiculum (fig. 44). Some helminthologists are of opinion that the mature females inhabit the colon, whilst the males and immature females are found in the ileum.

Oxyurides are often present in large numbers, and wander into the rectum. They often cause intense irritation in the

FIG. 43.—*Ascaris lumbricoides*; male, with exerted spicules. Nat. size (Cobbold).

FIG. 44.—*Oxyuris vermicularis*, female. Highly magnified. After Leuckart.

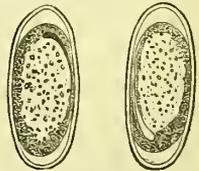

FIG. 45.—Eggs of *Oxyuris vermicularis*, enclosing tadpole-shaped embryos.  $\times 450$  diam. Original.

worms may occasionally perforate the intestinal wall, and, getting into the subserous tissue, give rise to abscess. Such cases have been recorded. The wandering habit of ascariides is often fatal to them.

neighbourhood of the anus, and in females cause great distress by creeping into the genital passages, especially during the night. The eggs of *oxyuris* are expelled with the fœces

and require to be taken into the stomach before they re-develop (fig. 45). Persons re-infect themselves by scratching the anus, and conveying the ova, by means of the finger-nails, to the mouth.

**SYMPTOMS.**—Among the local symptoms heat and irritation around the anus and nose are common. In children especially we often find restlessness, nervous irritation, choreic symptoms, and convulsions. Signs suggesting such severe conditions as meningitis are by no means infrequent. The existence of thread-worms is easily verified by administering a mild purgative and examining the fæces. As a rule, they will be found in considerable numbers. In the case of children the attention of the nurse is called by finding the worms on the sheets.

**TREATMENT.**—Brisk saline purgatives to expel the worms, and extreme cleanliness to prevent re-infection, are usually all that is required. Fruits and vegetables should be thoroughly cooked. In adults treatment requires to be carried out more vigorously, with such drugs as calomel, scammony, aloes, jalap, santonin, and asafœtida, in conjunction with enemata of infusion of quassia, or salt and water.

*c. Trichocephalus dispar*, or *Whip-worm*.—The male and female equal each other in

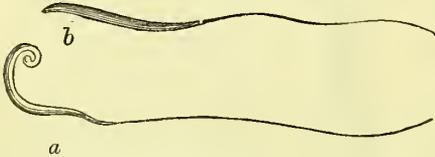

FIG. 46.—*Trichocephalus*; male (a), and female (b). Enlarged one-fourth.

length; as a rule they average 4 to 5 mm. The anterior part of these worms is fine and thread-like, the posterior is thicker, and contains the genital organs. In the male the caudal end is rolled into a spiral; near the extremity it is furnished with a spine (fig. 46).

The trichocephalus resides mainly in the cæcum. The early stages are passed in water or damp earth. The worm is very common in France: Davaine calculated that half the Parisians are infested by it. In England it is rare. Unless present in great quantities it is not often a source of trouble.

*d. Ankylostoma duodenale*.—This small worm is also known as *Sclerostoma duodenale*, *Dochmius*, or *Strongylus duodenalis*. Occasionally it is referred to as the *tunnel-worm*, on account of the disasters it caused among the men engaged in the Mount St. Gothard Tunnel. The female averages twelve mm. in length, the male is slightly smaller. The cephalic end is furnished with an oral capsule, which possesses a cleft covered by two chitinous lamellæ. The ventral lip has

four curved teeth; the dorsal, two straight ones. The caudal end in the male has a three-lobed bursa and two spines (fig. 47). This worm infests the small intestine and bores its way into the mucous membrane.

The effects of ankylostoma on the gut are very characteristic. The damaged spot is indicated by a small ecchymosis, with a central depressed white spot, in which the head of the worm lodged; occasionally it may be found still anchored to the mucous membrane. When present in large numbers these worms produce anæmia, sometimes called Egyptian chlorosis. The ankylostoma is very common in Egypt and Brazil. One stage of the worm is passed in muddy or dirty water; it gains access to the alimentary canal in drinking-water, and there attains its maturity.

FIG. 47.—*Ankylostoma duodenale*; male (A), and female (B).  $\times 5$  diam.

**SYMPTOMS.**—The presence of this worm is indicated by the usual signs of anæmia, viz. pallor of the mucous membranes, weakness, palpitation, and faintness. Diarrhœa and dropsical effusions sometimes occur. The anæmia is due to the loss of blood consequent on the injuries inflicted by these parasites on the intestinal mucous membrane.

**TREATMENT.**—The worms should be evacuated by calomel and santonin combined, given at intervals over a period of a few weeks, for it must not be imagined that one or two doses will destroy the thousands of helminths lodged in the intestines in a severe example of this disease. The liquid extract of male fern is a useful remedy. The patient will require nourishing diet, easily digestible food, and good wine, with the usual tonic remedies.

*e. Filaria medinensis*, *Dracunculus*, or *Guinea-worm*.—This is a fine thread-like worm from 60 to 100 cm. in length, and about 2 mm. broad. The female only is known. The embryos develop within the uterus. The intermediate host is a minute crustacean (*Cyclops*), which inhabits drink-

FIG. 48.—*Filaria medinensis*. Reduced to  $\frac{1}{2}$ .

ing-water. Within the cyclops they are introduced into the human stomach, and then migrate into the subcutaneous tissues, where they become mature. A common situation is the tissue beneath the skin of the legs and feet; the heel is a favourite situation.

The worm is confined to certain districts of Asia, Africa, and Brazil. It is supposed to be identical with the fiery serpents mentioned in the Pentateuch.

When the worm first lodges in the subcutaneous tissue it gives rise to little trouble; as it grows an abscess forms and gradually exposes the worm. Treatment consists in carefully winding the worm with gentle traction around a slender stick of ivory, bone, or wood, an inch or so daily, taking care not to break it. This method seems to have been employed of old by Persian surgeons.

f. *Trichina spiralis*.—The mature worm inhabits the intestinal canal. The female is 3 mm. long; the male is much smaller, and is further distinguished by presenting on the dorsal side of the tail two mammillary protuberances, which are turned towards the ventral aspect, and include between them four wart-like nodules (fig. 49). The young are developed in the uterus, and are born in a free state. The immature trichina inhabits

FIG. 49.—*Trichina spiralis* magnified; male (a), and female (b). After Leuckart.

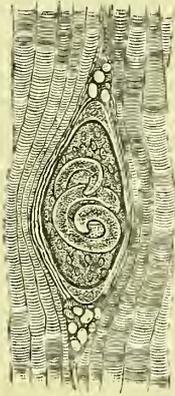

FIG. 50.—Portion of human muscle, enclosing a single capsuled *trichina*. Highly magnified. After Leuckart.

voluntary muscular fibre, where it is usually coiled into a spiral, embedded in granular tissue and surrounded by a cyst-wall, which frequently contains calcareous particles (fig. 50). These capsules are visible to the naked eye as minute white specks. Each capsule usually contains one trichina, but two, three, and even five may be present.

The relation of the two forms is as follows. When a piece of muscle containing living trichinae is taken into the stomach, the cap-

sules are digested and the worms set free. In two days and a half they become mature, and pair. The embryos commence to be born on the seventh day; and the female may continue to bring forth worms for many days. The mature worm lives but a few weeks, but during this brief life may bring forth a thousand or thirteen hundred embryos. The young then seek for striated muscle-fibre, and migrate through the wall of the intestine and the subperitoneal tissue. A few may get into vessels and are distributed by the circulation. On gaining access to a muscle they penetrate the fasciuli, becoming in about fourteen days mature muscle-trichinae. In due course they become encysted; the cyst is said to be in part due to a secretion furnished by the trichina. After a time the cyst-wall calcifies; should the trichina die, the cyst-contents also calcify. The duration of life of the worm in the muscle is very long, and even survives for a time the death of its host. The trichinae are found most abundantly in the intercostal muscles, diaphragm, and laryngeal muscles. In the limb muscles they are less abundant, and cluster near the union of the muscle with its tendon. The trichinae so accurately select the voluntary muscles that the pharyngeal constrictors and upper part of the oesophagus will lodge hundreds of them, while the rest of the tube contains none.

Symptoms.—Human beings usually acquire the disease from eating trichinosed pork. The symptoms may be divided into two stages: the first consists of gastro-intestinal disturbance due to the introduction of the parasite; the second corresponds to the migration of the worm, and is characterised by muscular troubles and febrile disturbance.

The gravity of the symptoms depends upon the number of trichinae taken. The initial gastro-intestinal catarrh lasts usually about a week. The second stage is characterised by high fever and pain in the limbs and muscles, often mistaken for rheumatism. The muscles sometimes swell, become oedematous, and occasionally are partially paralysed. In grave cases delirium ensues, the limbs become flexed and paralysed, there is excessive diarrhoea, terminating in death. The duration of the second stage lasts four or five weeks. In fatal cases, death usually occurs about the third or fourth week.

At the end of five weeks the migration is usually complete, and the trichinae once encysted give rise to no further trouble. That this is so is clear from the fact that, in dissecting-rooms, subjects occasionally occur with many hundred thousand trichinae encysted in the voluntary muscles of all parts of the body, from the head to the sole of the foot. The diagnosis may sometimes be established during life by an examination of suspected articles of food, or by the detection of adult trichinae in the evacuations during the

course of the disease. The most certain plan is to remove a fragment of affected muscle and examine it under the microscope.

**TREATMENT.**—If it can be at once ascertained that trichinosed food has been taken into the stomach, an emetic should be administered without delay, followed by a brisk purgative; this treatment should be pursued for several days to expel the worms before they become mature. Calomel alone, or combined with scammony or jalap, is recommended. Even when the young filariæ have begun their migrations, brisk cathartics still do good; but the patient's strength will require support during this critical stage by solutions of meat, broth, eggs, milk, and the judicious administration of wine or brandy. As the patient becomes convalescent ordinary tonics will be needed.

Preventive treatment consists in rejecting suspected trichinosed food, especially pork. The disease is rare in Great Britain, but fairly frequent in Germany, where it is the custom to eat 'Wurst,' or sausages made of smoked ham.

*g. Filaria sanguinis hominis.*—This parasite and its embryo are separately described. See **FILARIA SANGUINIS HOMINIS.**

**IV. Gregarinidæ** (*gregarius*, from *grex*, a flock).—Fr. *Grégarines*; Ger. *Gregarinen*.

Variety:—*Coccidium oviforme*.

The disease produced by the presence of the *coccidium oviforme* is known as *Psorospermia* ( $\psi\acute{o}\rho\alpha$  or  $\psi\acute{o}\rho\eta$ , a cutaneous disease—the itch, scab, or mange. The Latin equivalent is *scabies*). The French use the word *psore* as a generic title for vesicular and pustular maladies of the skin. J. Müller seems to have first used the word 'psorosperm' to indicate a parasitic affection of the skin, gills, muscles, and kidneys of fish and frogs. In the skin of fish the disease consisted of small sacs containing oval bodies, some with and some without tails; these he termed psorosperm saccules.

It has long been known that the destructive liver-disease of rabbits is due to the presence of small oval bodies named *coccidia oviformia*, lodged in the bile-ducts. The coccidium is thus described by Leuckart: It is egg-shaped, 0.033 to 0.37 mm. long, and 0.015 to 0.02 mm. wide, with a thick smooth shell, possessing at one end, usually the narrower, a micropyle. The coccidia resemble very closely the eggs of certain entozoa.

It has been known since 1858 that this coccidium occurs in the human subject, and since that date numerous cases have been observed. Among the recent cases, one described by Mr. Silcock may be mentioned. A woman, fifty-three years of age, was thought to be suffering from typhoid fever. The illness dated from a chill taken seven weeks before death. The symptoms were pain in the limbs, nausea, and occasional sickness, tenderness over the liver and spleen, fever

of remittent type, the temperature reaching 103° F., and slight diarrhœa. The urine was albuminous, the splenic and hepatic dulness increased, and the tongue dry and coated with brown fur. Death resulted from cardiac failure.

On *post-mortem* examination the liver weighed eighty-three ounces, and contained numerous small caseous foci; the spleen weighed sixteen ounces, and presented similar foci varying in size from a pin's head to a pea. Papule-like elevations dotted the mucous membrane of the ileum and large intestine. The naked-eye characters of these nodules resembled tubercle, but on microscopic examination they were found to be coccidium nodules.

The mucous membrane of the ureters is a favourite situation for these nodules. In this situation they give rise to hæmaturia, frequent micturition, and death from exhaustion.

There is reason to believe that these parasites invade the orifices of the follicular ducts of the skin and give rise to molluscum contagiosum and chronic eczema of the nipple (Darier). Confirmatory observations have been made in London.

**V. Rhizopoda** ( $\rho\acute{i}\zeta\alpha$ , a root; and  $\rho\acute{o}\delta\varsigma$ , a foot).—Fr. *Rhizopodes*; Ger. *Rhizopoden*.

*Amœba coli.*—Lambl appears to have been the first to detect amœbæ as human parasites, but the first satisfactory investigations were made by Lösch in 1875. He found them in the stools of a Russian peasant suffering from ulceration of the large intestine. In this case the amœbæ were five to eight times larger than the red blood-corpuscles; their protoplasm, which was coarsely granular, presented a few blunt processes, a round nucleus, and several vacuoles.

Lösch found them in great number; as many as sixty could be seen in one field of view with a magnifying power of 500. The peasant who was the subject of Lösch's researches had lived a miserable life; his illness presented all the signs of violent dysentery. Pleurisy and pneumonia supervened, accompanied by anæmia, exhaustion, and death. The fresh dejections from this patient were injected into dogs *per os et anum*, but with incomplete results. In 1883 Kartulis examined in Egypt 150 bodies of persons dead of dysentery, and found the amœba in every case. In twelve *post-mortem* examinations amœbæ were found in the ulcers. Subsequently Kartulis extended his observations to hepatic abscess complicating dysentery, and found amœbæ in sections of the abscess-wall. They resembled those found in the intestine. He has since extended his researches so as to include 500 cases of dysentery, with confirmatory results.

The amœba coli has been found in the intestines of dysenteric patients by other observers—Massentin, Baungarten, and Osler.

Dr. Osler's observations were made on a doctor, twenty-nine years of age, resident in Panama for nearly six years, who had suffered from chronic dysentery. When he came under Dr. Osler's care, abscess of the liver was detected and drained. As the pus came from the drainage-tube, samples were taken at once to the laboratory and examined. Amœbæ were present in large numbers, and continued to be present until the patient died. Amœbæ were also found in the stools, and in every respect identical with those from the abscess. They were rarely found in the brownish stools, but were more frequent in the mucus and in the greyish fragments of sloughs.

The amœbæ in size ranged from 10–20 mm., and were somewhat larger than those found by Kartulis. When once recognised there was not the slightest difficulty in distinguishing them, even when at rest, from pus-cells, not merely by their size, but from the entirely different appearance of their protoplasm.

How far these bodies are the exciting agents of the disease is uncertain, because amœbæ have been found in normal fæces; nevertheless they are deserving of extended study. They have been found in Egypt, Athens, St. Petersburg, London, and America.

J. BLAND SUTTON.

**ENTOZOON FOLLICULORUM.**—

A synonym of the animalcule of the follicles of the skin, otherwise named acarus (Simon), demodex (Owen), and steatozoon folliculorum (Erasmus Wilson). See ACARUS.

**ENTROPION** (ἐν, in; and τρέπω, I turn).

A morbid condition in which the eyelid is inverted, so that its free margin is directed towards the eye. See EYE AND ITS APPENDAGES, Diseases of.

**ENURESIS** (ἐν, in; and οὐρέω, I pass the urine).—Involuntary discharge or incontinence of urine. See MICTURITION, Disorders of.

**EPHELIS.**—SYNON.: Sunburn; Fr. *Ephélide*; Ger. *Sonnenflecken*.—This word is applied to pigmentary discoloration of the skin, of a brown, grey, or black colour, increased by the stimulus of light and heat, as of the sun's rays, or scorching by fire. Two principal varieties of the affection have been noted, namely, Ephelis solaris, and Ephelis ignealis. See PIGMENTARY SKIN-DISEASES.

ERASMUS WILSON.

**EPHEMERAL FEVER** (ἐπί, upon; and ἡμέρα, a day).—A mild form of milk-fever, so called on account of the rapidity with which it subsides, lasting not more than a day. See MILK-FEVER.

**EPHIDROSIS** (ἐπί, upon; and ἰδρώω, I sweat).—A term signifying a state of sweating, and synonymous with idrosis. See PERSPIRATION, Disorders of.

**EPIDEMIC** (*epidemicus*, affecting the people; from ἐπί, upon; and ἄνθος, a people).

The word 'epidemic' is used in two senses by medical writers and by medical men, namely, (1) in a general sense, and (2) in a technical sense.

As a *general term* the word signifies 'common to, or affecting, a whole people, or a great number in a community; prevalent; general' (*Webster's Dictionary*). It is in this sense that the word is used when it is applied to mental, moral, and social phenomena, as, for example, when we speak or write of 'epidemic suicide,' 'epidemic folly.' This employment of the word is consistent with received literary practice. Thus we read, 'There was a time when *wit was epidemic*' (*Athenæum*). Again, M. Littré, writing to the *Temps*: 'It argues great confidence in oneself and one's own enlightenment to treat with haughty disdain, and without reserving any compromise, the opinion of so many citizens, and to regard it as a case of *epidemic aberration*.'

As a *technical term*, having reference to disease, the word 'epidemic' has several different meanings attached to it. All these meanings include the notion of general prevalence among a community or a people, but some of them would go on, beyond what etymology justifies, to attach a peculiar hypothetical or theoretical conception to the term. Thus (a) Mayne restricts the term to diseases which are contagious, making contagion the essence of *epidemicity*, as he would phrase it; (b) Dunglison implies by the term a particular constitution of the air ('*constitutio aeris*, or condition of the atmosphere'); (c) other authoritative writers use the term as signifying a widespread cause, telluric, atmospheric, cosmic, as the case may be, acting at the same moment of time on many individuals, or as something occult, regarding which speculation is vain, and which they designate *epidemic constitution* or *epidemic influence*.

The foregoing technical significations attached to the word 'epidemic' are not less misleading than insufficient. Mayne's definition imposes an arbitrary limitation upon the meaning of the word, while it involves but a partial notion of the phenomena of epidemic prevalence of contagious diseases. Dunglison's definition does not rest upon a scientific foundation, and its phraseology, derived from a period when medicine was still hampered with semi-mystical speculations, cannot well be dispossessed of the vague traditional meanings which adhere to the word 'constitution.' Other technical definitions (if that can be called a definition which makes obscure what should be rendered clear) rest on mere assumptions, or relegate the term to the incomprehensible and insoluble. Of these last-named definitions Léon Colin has said: 'They signify

implicitly a common cause, apparently indecomposable, to which individuals are not exposed successively but simultaneously . . . a something isolated, impersonal, inaccessible to reason, detached from the disease itself, the epidemic genius [constitution, influence] . . . a creative force of the different epidemic affections, compelling, directing, extinguishing them.'

The promiscuous use of the word 'epidemic' in medical literature and medical talk, and the different irreconcilable significations attached to it as a technical term, have been, and still continue to be, sources of almost hopeless confusion in treating of diseases in respect to which the phenomenon of (etymologically) epidemic prevalence is observed. It is not difficult to apprehend how this has come about. The diseases in question (the *morbi populares* of some writers) include among their number plague, the eruptive and continued fevers, influenza, malignant cholera, &c. 'They have the peculiar character of attacking at intervals great numbers of people within a short period of time; they distinguish one country from another, one year from another; they have proved epochs in chronology; and, as Niebuhr has shown, have influenced not only the fate of cities, such as Athens and Florence, but of empires; they decimate armies, disable fleets; they take the lives of criminals that justice has not condemned; they redouble the dangers of crowded hospitals; they infest the habitations of the poor, and strike the artisan in his strength down from comfort into helpless poverty; they carry away the infant from the mother's breast, and the old man at the end of life; but their direst eruptions are excessively fatal to men in the prime and vigour of age' (WM. FARR). Exercising at all times in their greater and more fatal prevalence the profoundest influence over the mind, as well of the people generally as of the medical profession, these diseases, partly from the terror they inspire, partly from the extreme complexity of the phenomena they display, have formed a never-ceasing subject of the wildest speculation. No part of medicine has retained so much of the semi-mystical teachings of the older physicians as that which relates to epidemics, and general history has contributed with medical history to propagate in regard to epidemics that habit of thought which refers the unknown to the occult—using the latter term in the sense in which it is applied with regard to the imaginary sciences of the Middle Ages. Much of the speculation as to epidemics which passes current for science at the present day is in reality an unsuspected continuation of the mystical teachings of earlier medicine—magnetism, or electricity, for example, taking the place of Saturn or Mercury in the scheme of causation. The terminology is modernised, but the underlying conception remains the

same. Again, the so-called 'precursors' of epidemics, which still find a place in treatises on medicine, are the relics of the doctrine of portents of the Middle Ages. They rest on the assumption of an epidemic being determined by some common extra-mundane or intra-mundane cause, of which it is but one of several effects. The celestial 'portents,' such as comets and meteors, and the more manifest telluric 'portents,' such as earthquakes and volcanic eruptions, have been discarded; but the 'portents' derived from exceptional developments of insect life, from murrain, from unusual prevalence of certain diseases, and from remarkable perturbations of the weather, are retained under the denomination of 'precursors.' For example, the earlier epidemics of malignant cholera which visited Europe were believed to have been heralded by an unusual prevalence of 'fevers' and of diarrhœal affections. The epidemic of 1865-66 gave an excellent opportunity of studying the facts bearing on this question. Europe was taken by surprise when cholera appeared in 1865, on the south coast of the Mediterranean, at Alexandria, and began thence to extend rapidly to the southern and eastern shores of that sea. It was not, indeed, until the disease had effected a lodgment in several parts of the Continent that the attention of governments and the public with regard to it was fully aroused. No change of the public health in the several places visited by the epidemic had occurred of such a nature as to give rise to any, even the least, suspicion of impending pestilence. Moreover, notwithstanding the prevalence of steppe-murrain and of cerebro-spinal fever in Northern Europe at the beginning of 1865, there was nothing to suggest (indeed it was not suggested) that these phenomena were 'precursors' of the coming epidemic of cholera, or of the extension of yellow fever to the shores of England the same year. In fact, the different occurrences were parts of contemporaneous rather than successive phenomena. The condition of the public health preceding the appearance of cholera in England, and especially in respect to diarrhœa antecedents, was made the subject of careful study by the late Professor Parkes and others. These observers failed to obtain any inkling of a change in the public health which could be regarded as presaging pestilence—of the existence, in short, of any so-called 'epidemic constitution.' It is true that John Sutherland had described an increase of 'fevers' and diarrhœal disease in Malta, as preceding the appearance of cholera there, in June 1865, observing that: 'These facts are sufficient to show that, long before cholera began to come towards the north-west, there were indications of a changed condition of the public health in Malta;' and after giving an account of two groups of choleraic cases which occurred in May, he adds, 'It appears to me

scarcely possible to escape from the conclusion that, long before cholera appeared in Malta, possibly before the first outbreak in Arabia, the earliest wave of the coming epidemic had passed over those islands.' But while, according to Dr. Sutherland, the coming epidemic was thus clearly foreshadowed in Malta, no change in the public health presaged its appearance in Gibraltar in July. The absence of all foreshadowing of the epidemic at Gibraltar can hardly be reconciled with the suggested presence of such foreshadowing at Malta. The facts which have been interpreted as presaging the appearance of cholera in the latter island are, indeed, to be regarded as coincidental rather than related. It is true, also, that MM. Didiot and Gués have endeavoured to show that, prior to the appearance of cholera at Alexandria in 1865, choleraic disease existed in Marseilles, and that the outbreak of the epidemic in the latter town was preceded by 'une constitution médicale cholérique.' The evidence they advance in support of their conclusions simply shows that deaths from infantile cholera, which, as they properly remark, is, 'à la vérité, fréquente à Marseille,' and from so-called 'sporadic' cholera, are apt to occur in Marseilles during the months of May and June, as perhaps in every city and town of Southern and Central Europe.

Another illustration to the same effect as the above, in regard to the 'precursors' of epidemics, is furnished by the history of the small-pox epidemic of 1869-73, the greatest epidemic of this disease in recent times—a true pandemic (πάνδημος, from πᾶν, all; and δῆμος, the people) extension of the malady. The acutest observers were taken by surprise with the malignity and diffusibility of the disease during the epidemic—phenomena wholly unforeseen. Here, again, the study of the diseases preceding or accompanying the epidemic yields no facts of variation in their prevalence, from which the approach of a great epidemic might have been inferred, nor gives any hint that they were dependent with it on some common cause.

There were *concurrent* phenomena of disease during both epidemics, but they were concurrences of certain diseases existing at the same time among the population affected by the great epidemic, and some of them probably having certain secondary elements of causation in common. This is a different question to that of an assumed 'epidemic influence' or 'epidemic constitution.' The subject of the *concurrence of epidemics* is a new field of investigation, which has lately been opened by an arithmetical study of George Buchanan's, relating to epidemics in numerous extra-metropolitan registration sub-districts in England. This study was directed to ascertain—as necessarily introductory to a statistical investigation regarding community of causation or mutual antagonism of various

epidemics—the arithmetical probability of their concurring as a mere matter of chance. The data used were taken from a particular quarterly return of the Registrar-General, and they extended to 946 occurrences of epidemics (small-pox, measles, scarlet-fever, diphtheria, whooping-cough, fevers, and diarrhoea and simple cholera) in 1,490 districts. The result showed a good deal of general correspondence between the calculated number of concurrences and the actually observed number, but with departures, of more or less magnitude, of the actual from the calculated degree of concurrence, which deserve to be followed up by further investigation. The departures were shown in an excessive frequency of the concurrence of measles with the other epidemics, of diarrhoea with all other epidemics except small-pox, and of scarlet-fever with the 'fever' of the Registrar-General. On the other hand, it is of interest to observe that there was an absence of any notable excess of frequency of concurrence between scarlet-fever and diphtheria, or between scarlet-fever and whooping-cough.

In view of the extreme looseness with which the word 'epidemic' is used in medicine, sometimes simply as a descriptive term, sometimes as a technical or quasi-technical term involving various hypothetical and theoretical conceptions inconsistent with each other, and sometimes as implying an occult influence, it would be well if it could be discarded from medical literature and language. 'Epidemic,' in its present medical uses, is an instance of words which, as Bacon says, when writing of the effects exercised by a bad and inapt formation of words on the human mind, 'force the understanding, throw everything into confusion, and lead mankind into vain and innumerable controversies' (*Nov. Org. App.* 43). But the retention of the word, from its long and familiar usage, is practically a necessity in medicine; moreover, it would be difficult, if not impossible, to find a substitute which, if the word be used in its ordinary signification, would supply its place.

It is suggested here that the technical meaning of the word 'epidemic' should be assimilated to the common meaning; or, more accurately, that the technical meanings now attached to the word should be abandoned, and the word used in medicine in the same sense as in general literature and in ordinary converse; that is to say, as a merely quantitative term applicable to particular phenomena, whether pathological, mental, or social, in so far as they are 'common to a whole people, or to a great number in a community,' or, in a word, are 'prevalent' or 'general.' In this way not only would the confusion arising from the present medical uses of the word be got rid of, but the scientific study of epidemic phenomena would be facilitated in the only direction which gives promise of successful issue. As Léon Colin has aptly

written: 'It is the disease which constitutes the epidemic, not the epidemic the disease. The evil always remains the same, the number of affected alone being increased.' The medical study of epidemics is essentially a study of the individual diseases which are apt to become epidemic, and not, as has been too commonly the case hitherto, of some figment of the imagination (*epidemic constitution*, or *influence*, or *genius*), apart from the diseases. It is only in proportion as researches have been directed to particular diseases liable to become epidemic, and to the conditions under which they prevailed epidemically, that recent advances in our knowledge of epidemics have been made. In this country the two most important events which have occurred in this connexion of late years were the discrimination of *typhus* from *typhoid fever*, by A. P. Stewart and William Jenner, and the researches on the *typhus of horned cattle* (steppe-murrain, *cattle-plague*) promoted by the Royal Commission of 1865-66 on Cattle-Plague. The discrimination of typhus from typhoid fever proved that the voluminous speculations which to that time were current on the epidemiology of the continued fevers of this country, then regarded as but *one* disease presenting several varieties, were for the most part meaningless verbiage, by showing that the two most common forms of fever were distinct diseases, clinically, pathologically, and aetiologicaly. This discovery proved to be the inauguration of a true method of investigation concerning epidemics, by making evident that epidemic phenomena did not admit of accurate study, except in so far as it was based upon a just discrimination of the diseases manifesting them, and upon their clinical and pathological histories. The same lesson was taught, not less clearly, although in another fashion, by the researches promoted by the Royal Commission on Cattle-Plague, with which the names of Lionel Beale and Burdon Sanderson are especially connected. These researches demonstrated the essentially infectious nature of the malady, and that its prevalence was dependent upon the dissemination of the infection, directly or indirectly, from animals sick of the disease to the healthy. It was shown, indeed, in the pathological laboratory, that preconceived doctrines of some occult epidemic influence which had been submitted to the Commission as determining the prevalence of the cattle-plague had no existence in fact when the disease was subjected to experimental study, and that its conditions of prevalence were fully within human control. These researches proved the starting-point of those important investigations on the intimate pathology of contagion carried out by Burdon Sanderson and Klein, for the Privy Council, under the direction of John Simon, and to which William Roberts and others have independently contributed so

largely, and which have been followed by the investigations into the intimate pathology of scarlatina and diphtheria by Klein acting under the instructions of George Buchanan for the Local Government Board. See also PERIODICITY IN DISEASE.

**EPIDERMIS, Diseases of.**—See SKIN, Diseases of.

**EPIDERMOPHYTON** (*ἐπί*, upon; *δέρμα*, the skin; and *φυτόν*, a plant).—The name of the epiphyte, or parasitic fungus, of pityriasis versicolor; also called microsporon. See EPIPHYTA.

**EPIDIDYMITIS** (*ἐπί*, upon; and *δίδυμος*, a testicle).—Inflammation of the epididymis. See TESTES, Diseases of.

**EPIGASTRIC REGION.**—This region is situated at the upper and central part of the abdomen, just below the ensiform cartilage, and between the sloping margins of the thorax down to the level of the ninth cartilage, corresponding to what is popularly known as the 'pit of the stomach.' The structures within the abdominal cavity which normally occupy the epigastrium are the greater part of the stomach, a small portion of the liver, and more deeply a part of the pancreas, the aorta giving off the cœliac axis and superior mesenteric branch, the vena cava inferior, the veins forming the commencement of the portal vein, the receptaculum chyli, and the solar plexus.

**CLINICAL INVESTIGATION.**—Clinically, it will be found that patients frequently complain of abnormal sensations specially referred to the epigastrium. These are generally associated with the stomach, and may merely amount to a sense of discomfort, fulness, or tightness; or to actual pain of varying character, more or less severe according to the condition upon which it depends, and often much influenced by the ingestion of food. Sensations of trembling, throbbing, or sinking at the pit of the stomach are also of common occurrence, especially in females. These are often merely of a nervous character. In some cases there is evident tenderness, either over the entire epigastrium or in some limited spot, and it is important to recognise whether this is superficial or felt more or less deeply, for it may be connected with the superficial structures, the peritoneum, the liver, the stomach, or the pancreas. The sensation experienced in connexion with hunger is referred mainly to the epigastrium, and it may be of a painful character. Here may

also be noticed the epigastric pain termed *gastralgia* or *gastrodynia*, which is usually felt chiefly when the stomach is empty, being relieved by taking food. A most unpleasant sensation at the pit of the stomach accompanies nausea, which may be of a horrible but indescribable character; while violent vomiting or retching causes considerable pain or aching in this region, partly associated with the stomach, partly with the abdominal walls. Heartburn is another sensation which seems to start from the epigastrium. Sometimes the pain is situated deeply, or shoots towards the back. This may depend upon disease affecting the posterior wall of the stomach, pancreatic disease, aneurysm, or other causes. A sensation of tension or actual pain is sometimes experienced just below the ensiform cartilage in cases where the diaphragm is much pressed downwards, as from extreme emphysema, abundant accumulation of fluid or air in the pleura, or extensive pericardial effusion. A deep pain is not uncommonly referred to the epigastrium in cases of Addison's disease, and also in those of pernicious anæmia. Probably this is connected with the sympathetic plexuses.

*Physical examination* of the epigastric region is often of the greatest value, and important objective signs of various morbid conditions may thus be readily recognised. Of course organs which normally occupy other regions may enlarge so as to extend into the epigastrium, or may become very movable and consequently be felt in this region. It may, moreover, be occupied, along with other parts of the abdomen, by growths or accumulations of fluid. The objective signs and conditions which are more especially connected with the epigastrium may be indicated as follows:—

1. It is customary to apply the hand over the epigastrium for the purpose of counting the respirations, if these cannot be reckoned by merely watching the patient breathing.

2. Morbid conditions of the abdominal walls may be confined to the epigastric region, such as an abscess; and here it may be remarked that the recti muscles frequently become very hard and rigid when palpation is practised over this part, and so might be in danger of being mistaken for some serious lesion, unless care were exercised in the examination.

3. Growths connected with the peritoneum, especially the great omentum, may be felt chiefly or entirely in the epigastrium in some instances.

4. Abnormal states of the stomach are necessarily revealed mainly by corresponding signs in the epigastrium. Thus there may be evidence of dilatation of this organ; of carcinomatous infiltration or thickening of its anterior wall; of a localised tumour; or of some accumulation in its interior, whether solid or liquid. It must be remarked, however, that

the stomach, when diseased, frequently extends into other regions beyond the epigastrium, or is actually displaced.

5. When the liver is the seat of organic disease, this is often revealed in the epigastric region, usually along with other regions, but sometimes the abnormal physical signs are noticed specially in this part. Thus a cancerous mass may present here, or a hydatid tumour or hepatic abscess may tend in this direction. The gall-bladder has also occasionally been found, when the seat of some accumulation or of malignant disease, to have been displaced towards the epigastrium and become fixed there.

6. Pulsation is not uncommonly felt in the epigastrium. When situated at its upper part, just below the ensiform cartilage, it depends upon the heart, usually its right side, being due either to shortness of the sternum, displacement of the heart, or enlargement of its right cavities. Very often a pulsation is felt, and sometimes even seen, due to a pulsating aorta, especially in thin and anæmic subjects; and an impulse from this vessel may be transmitted through an enlarged pancreas, or through an abscess of the liver, of which the writer has seen a marked example. Occasionally an impulse in the epigastrium is connected with an aneurysm, either of the aorta or of one of its branches. A pulsation in this region has also been attributed to regurgitation of blood from the right auricle into the inferior vena cava and hepatic veins, in cases of tricuspid incompetency. A murmur may sometimes be heard in the epigastrium. Usually this is a conducted cardiac murmur, but occasionally it depends on an aneurysm.

FREDERICK T. ROBERTS.

**EPIGLOTTIS, Diseases of.**—See LARYNX, Diseases of.

**EPILEPSY** (*ἐπιλαμβάνω*, I seize upon).—**SYNON.**: *Morbus comitialis, sacer, major, &c.*; Fr. *Epilepsie, haut mal, &c.*; Ger. *Fallsucht*.

**DEFINITION.**—In its common form this apyretic affection is a neurosis, characterised by seizures of loss of consciousness, with tonic or clonic convulsions. When either of these manifestations recurs in fits, epilepsy exists, although incomplete, as shown by the following facts: first, that patients who generally have convulsions only are sometimes seized also with unconsciousness; secondly, that others who usually have seizures of loss of consciousness, without marked spasmodic action, sometimes have complete fits of epilepsy.

Some writers confine the name of *Epilepsy* to the well-defined form of that neurosis known as *idiopathic*. Others consider as belonging to epilepsy most of, if not all, the non-febrile affections recurring in fits, and of

which we sometimes have good instances in cases of paroxysmal aphasia, amaurosis, paralysis, or involuntary movements, either disordered or well co-ordinated, &c. There is no doubt that all apyretic nervous affections, appearing in seizures, have, on account of this special feature, a common link with epilepsy. In this article, however, the writer will only study the ordinary forms of the *morbus comitialis* and the epileptiform manifestations due to brain-disease.

**ETIOLOGY.**—Under this head we will study, first, what relates to the *causation of the morbid state* in which epilepsy essentially consists; secondly the *causes of attacks*.

**Predisposing Causes.**—*Heredity* deserves to be noticed first, not because it is the most frequent, but because it is a most undeniable cause. Pritchard has shown that all neuroses have the greatest relationship one to another. It is but natural, therefore, that epileptics are very often found to have had a father or a mother who suffered from some kind of nervous disorder. Moreau has shown that epileptics are often the offspring of insane parents. It is quite certain that people attacked either with organic disease of the brain, and having had no convulsions, or with any kind of neurosis or any form of insanity, very frequently have children who become epileptic. Important statistical data, given by Féré, show that, among the direct ascendants of 594 epileptics, 70 had suffered from epilepsy. 166 from insanity, 88 from paralysis, 21 from general paralysis, 72 from hysteria, 73 from senile dementia, 33 from puerperal eclampsia, 61 from chorea. The number of cases of nervous disorders among the direct ascendants of those 594 epileptics was 1,024. Inherited epilepsy, according to the writer's experience, which agrees with that of Féré, chiefly appears between the ages of 12 and 18; but its percentage remains high up to the age of 40, as, according to Dr. Gowers, out of 235 epileptics from 20 to 39 years old, 80 had inherited this affection, which gives 34 per cent. This shows how erroneous is the view of some able physicians, who maintain that after the age of 20 inherited epilepsy is not to be dreaded. It is certain, however, that this inheritance becomes relatively extremely rare in advanced life. But it can yet show itself at the ages of 70 (Poilroux) and 71 (Dr. Gowers). Still, we strongly advise that symptoms of an organic disease, and especially of a cerebral tumour, be most carefully sought for in all cases of supposed inherited idiopathic epilepsy in patients over 50.

The power of *alcoholism* in parents is so great that out of the 594 epileptics studied by Féré, 258 had parents addicted to habits of hard drinking.

As regards the influence of *sex*, there is a marked difference between men and women of somewhat advanced age, the proportion of

epileptic females being then larger than that of males; but for people under 25 years of age the reverse is true.

Independently of sex, *age* has certainly a decided influence on the appearance of epilepsy. The following table, borrowed from Hasse and Dr. Gowers, is important, as the results are grounded on most extensive statistical data. These results agree fully with the writer's own observations.

Age at commencement	No. attacked	
	Hasse	Gowers
Under 10 . . . . .	393	422
11 to 20 . . . . .	364	665
21 to 30 . . . . .	111	224
31 to 40 . . . . .	59	87
41 to 50 . . . . .	51	31
51 to 60 . . . . .	13	16
61 to 70 . . . . .	4	4
At 71 . . . . .	0	1
	995	1,450

The writer's experience seems to show that hereditary epilepsy makes its appearance chiefly between 10 and 12 in both sexes. At any rate it is certain that inheritance manifests itself rather before than during the period of change that puberty causes. Romberg, Dr. Russell Reynolds, and others have already pointed out that such is the general rule.

*Puberty* itself is a cause of epilepsy. This is clearly proved by the large number of epileptics who, as shown in the preceding table, have been attacked between the ages of 10 and 20 (364 out of 995, and 665 out of 1,450).

Of other causes, the most powerful are perhaps not those usually stated. In patients under 15 years of age the most frequent cause, after heredity, is some obscure alteration of nutrition of the brain, or congestion of that organ or of its membranes, lasting a more or less considerable time after typhoid fever or scarlatina. It is frequent, indeed, that in examining such patients (even when there are reasons to believe in heredity) there are a number of symptoms showing some deficiency in the action of the brain, as regards its motor, sensitive, or sensorial functions. It is most important to detect these symptoms, as the form of epilepsy due to or allied with the cerebral alteration then existing is often curable, or at least can be considerably benefited by treatment.

Alterations of *blood*, in quantity or quality, often contribute to the production of epilepsy. But, however true it is that a rapid and considerable loss of blood can cause an epileptiform attack, it has not been shown that such a cause has ever produced a lasting epilepsy. It is nevertheless well known that anæmia is a very frequent factor in the causation of that neurosis or of any other. A weak and slow action of the heart also is found in a number of cases to be among the causes of epilepsy (Sir W. Burnett, Blondeau). But

the reverse is sometimes observed; and, according to the writer's practice, cases of epilepsy are not very rare in which the pulse was strong and beating more than 90 or 100 times a minute, without any organic affection that could account for this phenomenon. In these cases the only morbid condition that could be looked upon as a cause of epilepsy was the abnormal circulation, which may be remediable.

There is no doubt that, when epilepsy appears in cases of Bright's disease, of affections of the liver or other viscera, it is due, at least in most cases, to the presence of some toxic agent in the blood; but other aetiological factors exist sometimes. Among them one especially deserves attention—it is an irritation of the nerves of the diseased viscus.

*Secondary syphilis* is a frequent cause of epilepsy. Undoubtedly syphilis then acts chiefly through the alterations it produces in the brain and meninges; but it often acts also on the cranial periosteum, and in disturbing nutrition and sanguification.

Of other dyscrasie *gout* has very little power; but *rheumatism*, although not frequently, can cause epilepsy by its morbid influences on the brain and its membranes, and by the production of diseases of the heart and the great blood-vessels.

*Diabetes* has been classed among affections sometimes causing epilepsy, but the question is then whether it is the presence of sugar in the blood or some affection of the medulla oblongata which brings on this affection.

Oxide of carbon, carbonic acid, lead, absinthe, alcohol, and a number of other *toxic agents* have sometimes produced a lasting epilepsy. Asphyxia by strangulation was in one case the cause of epilepsy (A. Beardley).

Purely *psychical* or emotional causes have much less power than has been supposed. But their influence is great in bringing on attacks when epilepsy exists.

*Determining Causes.*—The most frequent causes of epilepsy, however, are not the preceding, which generally are only predisposing circumstances. The really active efficient causes of epileptiform convulsions, and even sometimes of genuine and complete *morbus comitialis*, are to be found in the four following groups of organic morbid states:

(1) Lesions of some parts of the *brain*; (2) morbid conditions of the *meninges* or of the periosteum of the cranium; (3) lesions of the *spinal cord* or its membranes; (4) *peripheral* lesions anywhere. It is only for convenience sake that the writer establishes these divisions, as he looks upon all the four groups as quite alike. In neither of the four kinds of cases is the location of the lesion the seat of the neurosis, that place being only the seat of an irritative cause. Each of these kinds of causes will now be studied, the first one only with some development.

1. *Lesions of the brain considered as causes of epilepsy.*—This subject must be subdivided as follows: (a) parts of the brain that give rise to that affection; (b) kinds of brain-lesion which bring on that neurosis.

(a) What are the *parts* of the brain which can produce epilepsy? Facts answer that all parts have that power, as will be proved hereafter. On account of the importance of this subject as regards diagnosis and therapeutics of the nervous centres, the writer has noted down for more than twenty years all that relates to convulsions out of many thousands of cases of cerebral disease. Unfortunately, for a long time not having counted the cases without convulsions, he cannot say out of how many cases of brain disease come the 1,688 cases of convulsions he has collected.

The first important result of these researches is that partial or unilateral convulsions are more frequent than bilateral or general convulsions. Out of the 1,688 cases there are 887 in which the convulsions were altogether limited to one or two limbs, or began in one side before reaching the other, or were more violent in one side than in the other; while the number of general convulsions was 801.

The 887 cases of unilateral convulsions can be classified as follows:—

Side of Convulsions		Side of Lesion
Right . . .	102 . . .	Right
Left . . .	90 . . .	Left
Right . . .	294 . . .	Left
Left . . .	247 . . .	Right
Right . . .	73 . . .	Two sides
Left . . .	81 . . .	Two sides

As seen in this table, there were 192 cases of direct and 541 of crossed convulsions, with 154 cases of unilateral convulsions due to lesion in the two sides.

Of the 801 cases of convulsions in both sides of the body, there were 525 due to a unilateral lesion and 276 caused by a lesion in the two sides of the brain. In the 525 cases, the lesion in 235 was in the right side, and in 290 it was in the left.

It is remarkable that, contrary to what was long believed by the writer and other authors, the number of cases of convulsions (partial or general) due to a lesion in the right side of the brain is notably less frequent than that of cases of lesion in the left, as shown in this table:—

Side of Lesion	Convulsions	
Right	Left	
235	290 . . .	Two-sided
247	294 . . .	Crossed
102	90 . . .	Direct
—	—	
584	674	

It is very remarkable also that convulsions do not take place much more frequently on the right side of the body than on the left,

the numbers being for the right 469 cases, for the left 418 cases.

As regards the parts of the brain where a lesion is found, it is not possible to make use of all the facts, because, when a lesion is in the two sides, it very rarely occupies similar parts in both; and also in a rather large proportion of cases the lesion occupied two or more parts of the brain. The following table gives the number of cases for lesions in all the important parts of the encephalon:—

1. So-called motor centres . . . . .	196 cases
2. Cortex cerebri out of the motor zone	173 "
3. Surface or internal parts frontal lobe	144 "
4. " " " parietal "	140 "
5. Base of the brain . . . . .	91 "
6. Surface or internal parts of occipital lobe . . . . .	89 "
7. Cerebellum . . . . .	57 "
8. Surface or internal parts sph. temp. lobe . . . . .	54 "
9. Centrum ovale . . . . .	52 "
10. Optic thalamus . . . . .	42 "
11. Corp. str., opt. thal. & internal capsule	25 "
12. Corpus striatum . . . . .	24 "
13. Lateral ventricle . . . . .	21 "
14. Cornu Ammonis . . . . .	7 "
	1,115 "

It is essential to remark that the number of cases of lesion of the cortex cerebri in the so-called motor zone or out of it (369 out of 1,115 cases—*i.e.* about 33 per cent.) is possibly greater than it should have been, owing to the probable co-existence, in some cases, of a meningeal affection with the lesion of the brain-tissue. The writer must say that he has eliminated as completely as he could from the cases he has collected of disease of the cerebral surface those in which there was a complication of meningitis. If we add to these 369 cases one-half of those of disease of the four cerebral lobes (214 out of 427)—which ought to be done, because in more than one-half of these last cases the surface was partly the seat of the lesion—there are 583 cases of convulsions from disease of the cortex cerebri (583 out of 1,115—*i.e.* about 52 per cent.) The cerebral convulsions have more power than the rest of the brain to give rise to convulsions, but the cortex, outside of the so-called motor zone, has at least as much power as that zone.

Concerning the parts of the brain considered as not motor, we find that there are 89 cases of lesion of the occipital lobe and 54 of the spheno-temporal lobe, giving a total of 143 cases; to which we have to add the 173 cases of superficial lesion out of the motor zone; so that there are 316 cases of convulsion from a lesion in parts which, according to many authorities, ought not to have produced such a symptom. In more than one-half of the cases of disease of the cerebellum there was no pressure on the base of the brain, so that we could add a good many of the 57 cases of lesion of that nervous centre to the 316 cases above mentioned.

It would be wrong to imagine that, because the number of cases of convulsions was much larger when disease existed in the parietal lobe (140 cases), that that part has more power to originate epileptiform contractions than the occipital lobe (89 cases). The reverse is true, because, in opposition to all that is taught on this point, this last lobe has more power than the parietal in that respect (if we leave aside what relates to the ascending parietal). This can easily be proved. The number of cases of organic disease (especially hæmorrhage, as one can see in Gintrac's great work containing 127 cases of hæmorrhage in the parietal lobe and only 33 in the occipital) of the parietal lobe is more than treble that of cases of lesion of the occipital; while the number of cases of convulsions due to disease of the first of these parts not only is not three times as large as that of cases of convulsions due to the occipital lobe, but is even far from being the double. This last part, therefore, although supposed not to be motor, has more influence than the parietal lobe in giving rise to epileptiform convulsions.

Taking into account the frequency of disease in the four cerebral lobes, the number of cases of lesions which in each of them generate convulsions, shows that the frontal lobe is the one which has the greatest influence as regards the production of epileptiform convulsions. Next to it comes the occipital lobe, and, after these two lobes, we have to place almost on a similar level the parietal and the temporo-sphenoidal lobes.

Considering the frequency of disease, and especially of hæmorrhage, in the corpus striatum, which has been supposed to have a great influence in producing epileptiform convulsions, it is remarkable that that part of the brain has given rise to convulsions only 25 times (hardly more than 2 per cent.) The percentage given by the optic thalamus in that respect is higher (3.6 per cent.)

All the internal parts of the brain (centrum ovale, the lateral ventricles, and the central ganglia) give only 164 cases (15 per cent.), not much more than the frontal lobe (144 cases, almost 13 per cent.), although the central parts of the cerebrum are far more frequently diseased than the anterior lobe.

(b) There is certainly a very great difference between the various *kinds* of disease of or injury to the brain with regard to their power of giving rise to genuine epilepsy or to epileptiform convulsions. Still, it is very difficult to draw positive conclusions out of what has been published on this point, because the subject has not been studied as it should have been. Certain parts of the brain will give rise to convulsions, while others will not, under one and the same kind of lesion; but a part like the frontal lobe, for instance, which will so often generate genuine epilepsy or epileptiform convulsions under causes such as an injury, a tumour, an abscess, or an

inflammatory softening, will rarely produce convulsions under a cause which is an injury, but of a peculiar kind—*i.e.* a hæmorrhage. In other parts, on the contrary, a hæmorrhage will most frequently give origin to convulsions. The following table, from data furnished by Gintrac, is interesting in that respect; it shows what has been the frequency of convulsions in cases of hæmorrhage:—

Cases of hæmorrhage	Cases of convulsions
43 in cortex cerebri . . . . .	11
127 " parietal lobe . . . . .	25
33 " occipital " . . . . .	7
17 " frontal " . . . . .	2
38 " optic thalamus . . . . .	20
72 " corpus striatum . . . . .	0
48 " both central ganglia . . . . .	5
46 " lateral ventricles . . . . .	14
56 " cerebellum . . . . .	10
70 " pons Varolii . . . . .	25
5 " crus cerebri . . . . .	2
555	121

It is a most remarkable fact that out of 38 cases of hæmorrhage in the optic thalamus there were convulsions in 20—*i.e.* more than one-half of the cases; while there were none in any of the 72 cases of hæmorrhage in the corpus striatum. It is perhaps more remarkable that when both ganglia were the seat of the effusion of blood there were only 5 cases of convulsions out of 48 of hæmorrhage.

Tumour and tubercle are, with hæmorrhages and inflammatory softening, the lesions of the brain which give rise most frequently to partial or general convulsions. While tumours of the frontal lobe produce epilepsy or epileptiform convulsions in more than two-thirds of the cases, tumours of the temporo-sphenoidal lobe give rise to convulsions in about one-half, and tumours of the parietal and the occipital lobes in only about one-third of the cases. A remarkable fact which comes out of the study of cases of tumour of the brain published by Ladame, Bernhardt, Gintrac, and others, is that the base of the brain under the irritation of tumours gives rise to convulsions very much less frequently than the surface of the brain. Indeed, one part of the brain—the medulla oblongata—did not originate convulsions in one single instance out of 21 cases of tumour published by Bernhardt. This kind of disease of the medulla oblongata is not, however, incapable of giving rise to epileptiform attacks, as the writer knows of five cases of tumour of that organ causing convulsions.

There is no kind of lesion which may not give origin to convulsions. But there is one species of tumour, namely, aneurysm, which causes convulsions considerably less frequently than any other. Out of 86 cases of aneurysm of the various encephalic arteries, given by Gintrac, there were convulsions only in three, if we put aside, as ought to be done, the cases in which there

were alterations in brain-tissue or a rupture of the aneurysmal sac.

Abscesses of the brain have more influence in the causation of epileptiform convulsions than is generally admitted. Out of 87 cases of unilateral abscess collected by the writer, convulsions occurred in 43 cases.

Unilateral atrophy of the brain, of a very old date as regards its origin, is known to be allied not rarely to epilepsy (partial or general). Summing up 78 cases given by Cotard, Boyd, Turner, and Gintrac, the writer finds that epileptiform convulsions or genuine epilepsy existed in 20 cases. It is of great importance against the views of those who try to locate epilepsy in the so-called motor centres, that not only those parts were absolutely destroyed in more than one-half of those 20 cases, but that the so-called motor track in the brain and spinal cord was deeply altered if not destroyed, at least in certain parts of its length, and that nevertheless convulsions occurred, either anywhere, or chiefly or exclusively in the paralysed limbs.

Softening due to embolism causes convulsions almost as often as inflammatory softening, except when the seat of the lesion is the cortex cerebri. White softening of vessels of the occipital and of the frontal lobes produces convulsions more frequently than the same lesion in the parietal lobe. Embolism without any marked softening very rarely produces convulsions.

All kinds of entozoa in the brain very frequently give rise to convulsions, but none so often as cysticerci, if Kuchenmeister is right. He states that out of 30 cases of cysticerci in the encephalon there were 24 cases with convulsions. No other cause of irritation, whatever be its seat in the brain, originates convulsions so often as that.

The application of a ligature on one of the carotid arteries has brought on convulsions in a number of instances; and, what is remarkable, when the convulsions were unilateral they appeared on the corresponding side in more cases than on the opposite side.

2. *Lesions of the meninges considered as causes of epilepsy.*—The reader may refer to the articles on the Diseases of the Meninges and Diseases of the Cranium for what relates to convulsions due to these morbid states. Complete and persistent epilepsy due to chronic meningitis is very rare; but syphilitic affections either of the dura mater or of the periosteum of the cranium not very rarely will give rise to this affection. See MENINGES, CEREBRAL, Diseases of; and SKULL, Diseases and Deformities of.

3. *Lesions of the spinal cord considered as causes of epilepsy.*—In the writer's work on Epilepsy he has shown that this affection can arise from disease of the spinal cord. Since 1857, when that work appeared, many facts have come to his knowledge establishing that his conclusion was right. He only

maintained—and he does not now go beyond that assertion—that epilepsy sometimes has its cause in the spinal cord.

4. *Peripheral lesions*.—That genuine epilepsy can have its cause in any part of the body is now a recognised truth. But, besides that form of the *morbus comitialis*, what may be called the cerebral form, consisting in unilateral convulsions, can be originated by an irritation of either a nerve or a viscus. Among the parts of the body having the greatest power with regard to the production of epileptiform convulsions, we may name the bowels, the trigeminal and the sciatic nerves, the abdominal sympathetic nerve, and the sexual organs. Indigestible food may be the cause of an attack. In countries chiefly inhabited by the Anglo-Saxon race, children of the two sexes being less watched and less warned than elsewhere against the dangers of onanism, epilepsy due to this fatal habit is particularly frequent.

The great importance of a thorough knowledge of certain symptoms of cerebral epilepsy, especially as regards surgical treatment, makes it necessary that these symptoms should be carefully studied. It must be first stated that every kind of organic brain disease, wherever situated, may cause any form of epilepsy, and that, on the other hand, every form of this neurosis may exist without any cerebral organic affection. To this must be added that any part of the brain may be the seat of any kind of disease without convulsions appearing anywhere. In more than two thousand cases of brain disease analysed by the writer for other purposes, there were no convulsions. Out of that number there were more than one hundred cases of simply irritative lesion of the so-called motor centres, limited to them or invading the neighbouring parts, in which there were various symptoms, but no convulsions. In more than 160 cases of disease (destructive and irritative, or simply irritative) of the base of the brain there were no convulsions. Simply irritative lesions of the so-called motor tract, the internal capsule, between the great cerebral ganglia, did not cause convulsions in more than 45 cases. The part which gives the smallest number of cases without convulsions is the optic thalamus, and the part most able to bear any kind of irritation without producing convulsions is the corpus striatum.

These *negative* facts show as well as the *positive* ones—*i.e.* those in which convulsions take place—that that symptom appears or not according only to the excitability of certain parts of the nervous centres in different individuals. This result is borne out also by the study of unilateral convulsions, as is shown by an analysis of 887 cases collected by the writer.

The conclusions to be drawn from the study of these cases can be summed up as follows: (1) These convulsions can be produced by a

lesion in almost any part of the brain; (2) they can be caused by any kind of lesion; (3) they can begin in any muscle or group of muscles, or simultaneously in every part of one-half of the body (eye, face, neck, trunk, and limbs); (4) they can be preceded by any kind of aura, local or general; (5) they can be associated with any other symptom of brain disease, or be, for some time or till death, the only existing cerebral symptom; (6) they often precede general convulsions or appear at the end of such an attack; (7) they usually last longer than general convulsions even due to brain disease, but they especially last much longer than seizures of idiopathic epilepsy; (8) like other convulsions due to an encephalic affection, they often appear without loss of consciousness at the beginning or during the whole time they last; (9) they can take place either on the side of the brain-lesion that causes them or on the opposite side; (10) the proportion of cases of direct convulsions to cross ones, when the lesion is in the cerebrum, is about one to three, but the direct convulsions are more frequent than the cross ones, when that cause is in the base of the brain (crus cerebri, pons, and medulla); (11) the right limbs are more frequently attacked than the left (right 396 cases, left 337), and this rule is true for direct as well as for cross convulsions; (12) in the same individual, even when there is but one lesion, they can appear at first on the side of the lesion and afterwards on the opposite side, or *vice versa*; (13) they can occur on the side where exists a cross hemiplegia or on the opposite side; but they can also be direct, the paralysis also being direct; or they can be cross, the paralysis being direct; (14) Jacksonian convulsions (either when exclusively and persistently unilateral or only temporarily so) can appear on the side of the lesion, or from a lesion in parts of the brain belonging neither to the so-called motor zone nor to the first and second frontal convolutions, which Dr. Hughlings Jackson now supposes to be psycho-motor.

On account of the importance of Jacksonian convulsions for surgical treatment, it must be said that, as stated in the last of the above conclusions, they may appear, as shown by a number of cases, on the side of the lesion. In a case of that kind the surgeon, by pressing on the dura-mater on the *right* side, increased convulsions of the *right* limbs (Leroy).

Many cases show that surgeons led by the views of localisers might make great mistakes. For instance, in a typical case of Dr. Hughlings Jackson's, instead of the toes it was a finger which was first convulsed, although the lesion was in the paracentral lobe; in a case of Andral's, Jacksonian convulsions limited to the right arm were caused by a tumour between the left posterior lobe and the cerebellum; in a case of Prof. Virchow, Jacksonian convulsions beginning

in the left leg were due to a tumour of the right posterior lobe; in a celebrated case of Moreau (De Tours) there was a notable aura in the left hand and convulsions of the left arm due to a cyst in the anterior lobe near the right corpus striatum and the lateral ventricle. A good many facts show that Jacksonian convulsions, although caused generally by lesions of the first and second frontal or the two ascending convolutions, can be produced by lesions in many other parts of the brain very far from those convolutions.

Of the 887 cases of unilateral convulsions analysed by the writer, the arm or the leg alone, or one of these limbs at times, the other in other attacks, were the parts affected in 381 cases. The following table shows what parts of the brain were the seats of the lesion producing these partial convulsions.

	Arm	Leg	Leg or arm
Motor centres . . . . .	81	12	1
Surface frontal lobe . . . . .	17	1	1
„ parietal lobe . . . . .	13	1	2
„ sphen. temp. lobe . . . . .	8	1	0
„ occipital lobe . . . . .	12	1	0
„ several lobes . . . . .	22	2	2
Almost whole hemisph. . . . .	7	0	1
Frontal lobe . . . . .	16	1	0
Parietal lobe . . . . .	15	0	1
Sph. temp. lobe . . . . .	9	0	0
Occipital lobe . . . . .	10	1	1
Centrum ovale . . . . .	20	1	0
Lateral ventricle . . . . .	9	2	0
Two central ganglia . . . . .	5	2	0
Optic thalamus . . . . .	8	4	1
Corpus striatum . . . . .	4	2	1
Base of brain . . . . .	16	5	0
Cerebellum . . . . .	10	2	0
Several parts . . . . .	33	1	0
	<hr/>	<hr/>	<hr/>
	315	39	11

This table shows that the so-called motor zone and the rest of the cerebral cortex gave rise to a very large proportion of convulsions of one limb alone. There were 153 cases of convulsions of the arm, 18 of the leg, and 6 of leg and arm alternately. It will also be seen that the base of the brain, if it gave a small proportion of cases of convulsions of the arm, gave a large one of convulsions of the leg. But the most remarkable point is that *all parts of the brain can give rise to convulsions of the arm, and that most parts can produce convulsions in the leg.*

Most important conclusions can be drawn from the study of the percentage of cases of convulsions of the arm in the number of cases of unilateral convulsions. Thus it can be easily ascertained that the percentage is enormous—82 per cent.—for cases with a lesion of the sphenotemporal lobe; it is also very large for cases of lesion of the surface of the occipital lobe (50 per cent.); of the sphenotemporal lobe (47.6 per cent.); and of the frontal lobe (45.9 per cent.). Next come the so-called motor centres (45 per cent.), the mass of the occipital lobe (40 per cent.), the centrum ovale (37.7 per cent.), the cere-

bellum (37 per cent.), the parietal lobe (35 per cent.), and the frontal lobe (33.3 per cent.) A lesion of almost the whole brain (19 per cent.) and of the base of the brain (23.8 per cent.) give the smallest percentages.

As regards the leg, the largest percentage is furnished by the cerebral ganglia, next to which come the base of the brain, the cerebellum, the surface of the sphenotemporal and occipital lobes, and the so-called motor centres. It is evident from the facts relating to the leg, but still more from those concerning the arm, that great mistakes in the diagnosis of the localisation of disease might be made if convulsions of the leg or arm were looked upon as a proof that the cerebral lesion causing them is located in the motor zone, even if we include in it, according to Dr. Hughlings Jackson's views, the two first frontal convolutions.

Convulsions from brain disease may be alternate—*i.e.* they may affect the limbs on one side and the face on the other—and this owing to a lesion of either one or both sides of the cerebrum or the base of the brain.

It is important to know that unilateral convulsions are sometimes due to a peripheric irritation (in the bowels, the liver, the kidney, &c.), without any kind of disease existing in the brain.

There is no doubt that convulsions of one arm are often associated with spasmodic movements of the face; but there is no doubt also that the most heterogeneous associations of partial convulsions are sometimes witnessed: convulsions in one leg and in one eye, of the thoracic muscles and the face or of the neck and legs, and a great many other associations, from lesions which cannot give the key of these singular facts. The two arms or the two legs are not rarely affected together, even under the influence of lesions of only one side of the brain.

The kind of association between paralysis and convulsions is most interesting. French surgeons, till a somewhat recent period, gave it as a law that when convulsions from brain disease occur without paralysis they show themselves on the opposite side to that of the cerebral lesion; but that when there is paralysis, this symptom appears on the side opposite to that of the lesion, and convulsions occur on the corresponding side. This is the reverse of what is seen in the great majority of cases, in which paralysis and convulsions coexist on the same side. But there are two kinds of cases in which the convulsions are on one side and paralysis on the other. The writer has collected more than 200 cases in which the convulsions were on the side of the lesion, and paralysis on the opposite side; and 16 cases in which the contrary existed—*i.e.* convulsions on the opposite, and paralysis on the corresponding side. Here also we have a proof of the great variety of effects that can come from an irritation of the same or of various parts of the brain.

Unilateral convulsions have no essential connexion with psycho-motor centres, as is proved by cases of lesion of those centres on one side causing that kind of convulsions sometimes in one side of the body, sometimes in the other. The writer has seen two such cases and collected 42 other cases, some from most able observers, including Dr. Hughlings Jackson.

Many cases of epilepsy in man are on record, resembling the special kind seen in certain animals, particularly in this respect, that an attack can easily be produced by a peripheric irritation. The writer has collected more than sixty such cases. They form two principal groups—one in which an irritation of almost any part of the body was able to give rise to an attack; the other in which certain parts only had that power. Many of those cases belonged to the class of organic cerebral epilepsy; some depended on diseases of the pericranium, of the spine or its contents, of nerves or of one of the thoracic or abdominal viscera; while in other cases there was a genuine idiopathic epilepsy. The parts of the body which are most frequently found giving rise to an attack, are the pit of the stomach (under the influence of even a very slight pressure) and the skin of the neck laterally from the lower jaw to the collar-bone.

**SYMPTOMS.**—We shall consider this part of the subject under three heads—the *premonitory*, the *paroxysmal*, and the *inter-paroxysmal* symptoms.

**1. Premonitory.**—The frequency of premonitory symptoms, according to the writer's experience, is much greater than is generally known. It is extremely important to find out the existence of these warnings, as in many cases attacks may easily be prevented if we know when they are on the point of taking place. When we say that premonitory indications are extremely frequent, we do not mean that the classic or *Galenic aura* is often found. That vague, queer, and unexplained sensation, whether accompanied or not by a muscular contraction, is certainly more frequent than is admitted, but is considerably less frequent than the other kinds of warning. Among the premonitory symptoms there are four oftener observed than others: one is a change of temper (irascibility, appearing or increasing); another is a contraction of the vessels in the feet or hands, producing a diminution of temperature; and the two others are a spasmodic state of some muscle, or an optical illusion or hallucination. The following list mentions but a part of the various manifestations which indicate that an epileptic attack is threatening. Alterations of the various functions of the brain, sensations of any kind, headache or backache, vertigo, sensorial disturbances, sleeplessness or sleepiness, palpitation of the heart, dilatation or contraction of blood-vessels anywhere,

altered breathing, diminution or increase of the various secretions (of the skin, mucous membranes, or of the visceral glands), hæmorrhages from the nostrils or other parts, fever, more or less marked weakness (general or local), hunger or thirst, disgust for food or drinks, an increase of the sexual appetite or the diminution or loss of sexual desire or power, spontaneous erection, and spasm of the bladder—sometimes accompanied by involuntary evacuations of urine—involuntary expulsion of feces, cramps, trembling, choreic movements, tendency to run forwards, backwards, or round, rigidity or convulsions of a limb or other parts, paralysis of a limb or other parts—such is an abbreviated list of the forerunners noticed by a number of observers, and all of which the writer has seen or knows to have occurred in his patients.

Sometimes one or several of these symptoms will appear a day or two before the attack, but generally the warning shows itself a few hours, or a very much shorter time (even only a few seconds or a minute or two), before the seizure. Not rarely in cases of epilepsy due to an organic cerebral disease, or to cerebral congestion, a drawing of the head towards one shoulder will take place either before or during an attack. Premonitory symptoms unfortunately may be deceptive, as they can appear without being followed by the attack; and even in cases in which warnings usually exist there are sometimes attacks without any forerunner.

**2. Paroxysmal.**—The paroxysmal symptoms vary considerably according to the kind of attack. If the fit is one of *petit mal* (*epilepsia mitior*), there may be no other symptom than a loss of consciousness, with either a fixed state of the muscles of the eye or a slight contraction of one or more muscles of the face or neck, or a movement of the lips, tongue, and throat, as in the act of swallowing. According to his personal observation, the writer is inclined to affirm that an attack of *petit mal* never consists in a loss of consciousness only—*i.e.* without the least trace of any other trouble whatsoever. Dr. Russell Reynolds, however, states that he has seen such attacks, and therefore we must admit that sometimes a pure and simple loss of perception and volition is all that exists in a seizure of *epilepsia mitior*. In such an attack the patient may, if walking, continue to walk; but, if talking, he stops—generally for so short a time, however, that the trouble may pass absolutely unnoticed by listeners. Such an attack usually lasts only from one to four or a few more seconds.

**Haut Mal.**—In a complete attack of epilepsy, an irritation proceeding from a moral or physical source is the cause of an act of inhibition of the mental activity, and of a reflex contraction of blood-vessels in the cerebral lobes. Loss of consciousness is, of

course, the consequence of that inhibition. Together with Kussmaul and Tenner, the writer had long looked upon spasm of cerebral vessels as the cause of the loss of consciousness. He had a confirmation of that supposition in his epileptic guinea-pigs, in which he found that the blood-vessels of the brain contracted when consciousness disappeared. Since then, however, he has ascertained that consciousness was lost in the seizure, even after the excision of the upper cervical ganglia of the two sympathetic nerves—when, of course, the cerebral vessels remained dilated before, during, and after the fit—just as it is lost in animals having contraction of these vessels. Dr. W. Alexander has observed that in man, loss of consciousness in fits occurs after the excision of these ganglia, the same as before that operation. It is evident, therefore, that a spasm of the vessels of the brain is not an essential element in the causation of the loss of mental faculty. Still, when that spasm exists, and so long as it lasts, the lack of blood in the cerebral hemispheres must necessarily contribute to the cessation of the mental activity. The reasons for admitting that an act of inhibition is the first or principal cause of the loss of consciousness will be found in the writer's published papers on this subject.

Muscular spasms of a tonic character begin at the same moment that consciousness disappears. They may begin first in any part of the body, whether the attack is to be general, or to remain in one half of the body, or in one limb. Rather frequently the muscles of the face, the eyes, and the neck are seized before those of other parts, but the time is so very short between the appearance of spasm in these muscles and the general stiffness, that it is almost always very difficult to detect that these phenomena are not simultaneous. Together with the first appearance of a spasmodic condition in the face and neck there is also in a great many cases a contraction of some muscles of the larynx and of the expiratory muscles of the thorax and abdomen, producing the so-called epileptic *cry*, the character of which is so special that, when once heard, it can always be recognised even when the patient is not seen. When an epileptic is standing, at the onset of a complete attack, he falls. This is not due solely to loss of consciousness, as we know that in fits of *petit mal* this accident may not occur. The fall is sometimes an *active* one: the patient is precipitated more or less violently forward, backward, or laterally by muscular contractions. Then the fall may be either a *paralytic* or a *convulsive* one.

Generally a period of rigidity exists before the clonic convulsions appear. This stage of tonic spasm almost always lasts only a few seconds; but it may constitute the whole attack, and then it may last longer. On the contrary, clonic convulsions may appear

at the onset of the seizure. In almost all cases, however, they follow a general stiffness, and form a second stage or period of the fit of which by their violence and duration they are the principal part. The clonic spasmodic contractions as a rule last hardly more than from one to three minutes in idiopathic cases.

When a fit lasts five, six, eight, or ten minutes, even if there be no sign of an organic disease of the brain, there is some reason to suspect that the attack is brought on by such a cause. Generally, in complete seizures, the limbs on the two sides of the body have similar convulsions, but in cases of brain-disease there may be clonic convulsions on the one side and tonic rigidity on the other. In the face, the eyes, the neck, differences between the sides are frequent, or at least not rare, even in idiopathic epilepsy. In most cases, the eyes are drawn up under the upper eyelid, and they roll from side to side. It is not rare that the eyes, face, and head turn convulsively towards the left or the right side, sometimes jerking, however, alternately from one to the other side. When the head is carried sideways—to the right, for instance—it is chiefly owing to a spasm of the left sternocleido-mastoidens, but also to the group of muscles of the top of the neck on the right side.

Breathing is considerably interfered with during the whole attack. After the spasmodic action of the expiratory muscles contributing to the shriek, there is almost always for a time (not longer usually than one or two seconds) a stoppage of respiration from the persistence of that initial spasm. During the whole fit respiration is convulsive, irregular, jerky, or gasping, and always incomplete. A real asphyxia, going as far as cyanosis, soon shows itself. The face, which was pale at the onset, becomes red, and promptly assumes a livid, dark, purple or bluish-violet hue. A frothy saliva, frequently of a reddish tinge, from effused blood coming from the biting of the tongue or lips, issues, little by little, from the mouth. It is extremely rare that the movements of the heart are modified at the onset; but palpitation, or a diminution (and even a complete inhibition) of the cardiac movements has been noticed by the writer in a few instances. Soon, however, the heart becomes very much excited and beats quickly, as in ordinary asphyxia. The temperature rises ( $1^{\circ}$  or  $2^{\circ}$  F. and sometimes a little more); and the whole trunk, the face, and limbs, are covered with perspiration. The pupils always dilate considerably, sometimes after an evident contraction; the eyes are bloodshot; and hæmorrhage may occur there or in other parts, such as the nostrils, the ears, the bronchi, or even the capillaries of the skin or of the brain. Urine may be expelled from a spasm of the bladder at the onset, or from paralysis of the sphincter at the end of the fit.

As a rule, at the end of the convulsions the patient passes, without recovering consciousness, into a heavy sleep, with more or less violent stertorous breathing. A real comatose state is not rare. There is no doubt that these symptoms are more intense if no care be taken as regards the tongue and head. The patient should not be left on his back; and the tongue, which falls and covers the laryngeal opening, should be drawn forward. Some alleviation is almost always obtained when this is done for the tongue, and when the body, and especially the head, are placed on one side. Generally the sleep following a paroxysm does not last much more than an hour, sometimes not as long as that; but it is exceedingly rare that there is no sleep at all. The more violent the convulsions have been, the more there is relaxation of the muscles after they have ceased. When lifted up, the limbs may fall as if they were completely paralysed.

On waking from the sleep following a seizure most patients are very tired, the limbs and trunk aching, as well as the head. Usually there is some mental alteration, often consisting of confusion or stupor, and sometimes delirium. The mind, however, may be quite clear, even after a violent attack, and the head free from pain, the only effect of the fit being general lassitude. On the contrary, after an apparently slight seizure there is sometimes considerable mental disorder. The degree and duration of stupor after an attack have no relation to the duration of the convulsive period. Stupor is chiefly an effect of asphyxia, and is therefore in direct relation with laryngismus, trachelism, and the spasms of the thoracic muscles, of the diaphragm, and perhaps of the bronchial tubes also. It has been stated, and denied, that the urine passed after an attack of epilepsy sometimes contains albumen in patients free from kidney-disease. In at least five cases the writer has ascertained that there was a notable amount of albumen in the first issue of urine after attacks in which there had been violent spasmodic contractions of the abdominal and thoracic muscles. There was no disease of the kidneys or of the heart in those patients.

Attacks of epilepsy are sometimes very slight, consisting only, besides the loss of consciousness, of an extremely short tonic spasm of muscles of the trunk, the neck, the head, and the limbs. But even in the shortest and slightest attack of that kind the epileptic cry may be uttered, the tongue may be bitten, and there may be a somewhat comatose sleep after the fit.

It is now very well known that frequently there is after a fit a real paralysis, which sometimes persists for a long time. This loss of power is supposed to be the result of exhaustion from discharge of nerve-force, while it is evidently the effect of an act of inhibi-

tion associated with the convulsions—inhibition striking other motor elements than the excitation which causes convulsions. If it were an exhaustion from over-action the following facts could not exist: (1) the paralysis may appear after attacks which are not violent, and not show itself after most violent and prolonged convulsions; (2) there may be a paralysis in one or two limbs after an attack of *petit mal*, in which no convulsion has taken place in those parts; (3) after equal convulsions on the two sides of the body there may be a paralysis of one side only; (4) after unilateral convulsions there may be a paralysis of one limb only (especially the arm), while both have been convulsed; (5) the writer has seen a case in which a patient alternately had attacks of only paralysis or convulsions, or of convulsion followed by paralysis, always in the same limb—the left arm; (6) the writer has seen three cases of hemiplegia from brain-disease, in which the paralysis slightly but evidently *diminished* after each attack of convulsions. Several similar facts are on record; (7) Féré has found a loss of power after convulsions in 21 per cent. of his cases in the right arm, and in 23 per cent. in the left arm, while in cases in which, without convulsions, there was vertigo with or without loss of consciousness, the loss of power was 30 per cent. in the right arm and 27 per cent. in the left; (8) Dr. Hughlings Jackson has seen in those cases in which an abortion of the attack can be produced, that paralysis not only may appear, but can be greater than if convulsions had occurred. All these facts are in harmony with the idea that paralysis occurring in seizures either after or without convulsions is due to inhibition and not to exhaustion.

There are many reasons also to consider inhibition and not exhaustion as the cause of all the other losses of power which are sometimes observed after an attack of epilepsy, such as aphasia, amnesia, anæsthesia, loss of the muscular sense, amaurosis, deafness, anosmia, loss of taste, loss of knee-jerk. This is so true, that certain of these kinds of loss of function are sometimes, or even very frequently, as is the case for knee-jerk (Beevor), replaced by an increase of power.

*Petit Mal.*—The symptoms of a seizure of *epilepsia mitior* are very different from those of a violently convulsive attack of epilepsy (*haut mal*). The loss of consciousness occurs only for one or a few seconds, and the spasmodic contractions take place in a few muscles only—in the face, tongue, throat, eyes, and neck. If seized while standing up the patient rarely falls, and, on the contrary, if walking he may continue his movement as regularly as before the fit. If attacked while speaking, he generally stops while the consciousness is lost, and on recovering it he may complete the unfinished sentence, so that the bystanders may know

nothing of what has occurred. Sometimes, however, the patient's mind is deeply altered, even when the attack of *petit mal* has been as short and slight as possible.

*Nocturnal attacks* of epilepsy may occur without any knowledge of their having taken place. Indeed, the writer has sometimes been consulted by persons who only asked for advice on account of headaches, and who had no pain in the head except after nocturnal attacks of epilepsy occurring without their knowledge. In such cases, the patient, after a seizure during sleep, wakes up tired, as if he had walked considerably; he has pains in the limbs, the back, and the head. He finds his mind confused, and his memory affected; he feels disinclined to get out of bed or to exert himself in any way; and often he is excitable or depressed. Sometimes his tongue or his lips are sore, and if the pillow is examined it shows bloody spots. More rarely it is found that an involuntary evacuation of urine has soiled the bed. Anyone sleeping within hearing distance of the patient may be wakened by the piercing epileptic cry, and then hear the noise of the shaking of the bed, caused by the convulsive movements. Such attacks, although very frequent and also very violent, may remain altogether unknown and unsuspected by the patient and his friends.

3. *Inter-paroxysmal*.—The general health of epileptics is usually very poor. Besides the alterations of their mental powers, and especially of their memory, they show a great deal of excitability and often depression of spirits. Their circulation and their digestion are often affected. There is nothing special, however, either in the morbid state of their mind and of their feelings, or in the disturbances of their physical health. Certainly the mental aberrations observed in the inter-paroxysmal state are not essential elements in the symptomatology of epilepsy. These aberrations can exist without epilepsy, and in a great many cases they are missing.

The *frequency of attacks* varies immensely in epilepsy. In one case the writer learned that for more than seventeen years the patient had passed no night without a fit, and for more than ten years the average nightly number of fits had been about twelve, which gives a total of more than forty thousand attacks in ten years. On the other hand, he was once consulted by a patient, sixty-two years old, who had had but seven attacks, the first of which occurred when he was nineteen years old, the interval between that and the second fit having been thirteen years, and the interval between the two last seizures having been seven years. Between extremely different cases like the two just mentioned we find the greatest variety as regards the frequency of attacks. Usually, however, there are a number of fits every

month. If there are attacks with extremely violent convulsions, the frequency is generally much less than when the convulsions are slight. Seizures of *petit mal* are usually very frequent. A perfect periodicity is extremely rare, but an approximation to periodicity is not rare, especially in women. There may be singular and inexplicable periods; the writer knows of a number of cases with a weekly periodicity, and of a case in which for years attacks recurred every forty-nine days.

*Status Epilepticus*.—Bourneville, Féré, and Dr. Gowers have studied carefully this dangerous condition, which is often fatal to epileptics. As the writer will show about the treatment of *morbus comitialis*, it is important to know that this recurrence of a large number of fits, within a short period of time, with no return of consciousness between the attacks, may be the only kind of epileptic manifestations in some patients, in whom, after variable but sometimes almost perfectly periodical intervals, this so-called status epilepticus reappears. Usually, however, this frightful and very rapid succession of violent fits occurs in the worst cases of organic epilepsy due to disease of the brain, kidneys, or liver, and frequently then destroys the life of the patient.

COMPLICATIONS AND SEQUELÆ.—Epilepsy has no necessary or usual complication. The diseases which often accompany it are frequently its causes and not complications. Bright's disease and other organic affections of the kidneys, diseases of the liver, the womb, and other viscera, when allied with epilepsy, if they have not been the first and only cause of it, are powerful additional causes. As regards sequelæ, the important researches of Dr. Hughlings Jackson, Dr. Hughes Bennett, and Dr. Féré have established that difficult speech, aphasia, amnesia, trembling, general physical and mental weakening, as well as any mental disorder, paresis or paralysis, anæsthesia, or great disturbances in the various organic functions, may not only appear temporarily as post-paroxysmal phenomena in epilepsy, but may persist and increase after each fit. The most common of those effects of seizures of this neurosis, and especially of *petit mal*, is amnesia, which may last, even if the epileptiform affection is cured.

*PATHOLOGY*.—The writer does not pretend to know what is the nature of epilepsy, so that when he tries to explain how that affection is produced and how its manifestations are generated, he will only state facts, and the conclusions they forcibly lead to.

I. As early as 1857 he endeavoured to show that one of the most essential features of epilepsy is an increased excitability of the reflecto-motor parts of the nervous system, which may exist not only in many parts of the centres, but also in some peripheric parts

of the nervous system. The analysis of the phenomena which appear, after certain injuries, in guinea-pigs or cats in which epilepsy can be gradually produced, leads forcibly to this view. In these animals, a few days after a lesion which causes epilepsy (especially a section either of the sciatic nerve or of a lateral half of the spinal cord, in the dorsal region) the first morbid change to be detected consists in an increase of the reflex power of certain parts of the skin of the face and neck, while a greater excitability supervenes in the medulla oblongata, in the upper part of the cervical region of the spinal cord, and in some parts of the trigeminal and of the two or three first cervical nerves. Gradually the reflex excitability of the nerve-cells in direct communication with the fibres of the nerves we have named increases, so that irritation of the skin of the face and neck, instead of producing only, as at first, a reflex contraction of the neighbouring muscles, causes tonic or clonic spasms of all the muscles of the trunk, neck, and head, on the side of both the lesion and the irritation of the skin. Later on, the reflex spasmodic action extends to the other side, and at last (a month or later after the traumatic injury from which proceeds this series of effects) a complete attack of epilepsy takes place, characterised, as in man, by loss of consciousness, with tonic and clonic convulsions.

In cases of injury to certain parts of the base of the brain in some animals, the same changes may occur, but with two differences: 1st, the rapidity of increase in the reflex excitability of the parts above-named is very much greater than after an injury to the spinal cord or to the sciatic nerve; 2nd, the zone of skin that acquires the power, when irritated, to give rise to an attack is on the side opposite to that of the brain-injury, while it is on the side of the lesion of a nerve or of the spinal cord.

The writer cannot give here the many reasons showing that what takes place in animals rendered epileptic by the lesions mentioned, may be applied in a great measure to the production of epilepsy in man. He will only say that cases identical with those of his guinea-pigs have been published by several clinical writers.

After the important discovery of Fritsch and Hitzig, concerning the galvanic excitability of a certain zone of the cortex cerebri, it has been found that epileptiform convulsions can easily be produced by an irritation of that zone in monkeys, dogs, and cats. It is clear, therefore, that perfectly healthy animals can be rapidly rendered epileptic. Man also can be seized almost at once after a hæmorrhage in the brain or a fracture of the cranium.

II. In cases in which for the first time these spasmodic phenomena take place, the

irritation which brings them on does this *only after having given rise to a morbid change constituting epilepsy* or an epileptiform affection. A longer time is necessary for the appearance of these convulsive movements than for any kind of natural reflex contractions.

The facts relating to the production of an attack of epilepsy by the galvanisation or certain parts of the cortex cerebri in monkeys, dogs, and cats, also show that a certain time is necessary for the production of the morbid state in which epilepsy consists. In that case also, as hereafter shown, the spinal cord is partly the seat of the genuine epilepsy generated. In other words, two distinct effects result from the irritative lesion—the one the genesis of the disease, *i.e.* of the morbid condition allied with which is the power of giving rise to epileptic or epileptiform attacks; the other, the production of a seizure.

III. Experiments in sudden crushing of the head in animals show that epilepsy can appear, although nothing remains of any part of the brain, *not even a portion of the medulla oblongata*, the connexion between the encephalon and the spinal cord having been altogether severed. Epilepsy, in the case of the crushing of the head, has its seat in the spinal cord, whatever be the share of the brain in giving origin to it. The writer, although recognising that fact about the location of this affection in such special circumstances, is not, and has never been, ready to admit that the spinal cord in all cases is the seat of this neurosis.

IV. The writer believes that the supposed absolute distinctions between the various kinds of convulsions (eclampsia and other forms of epilepsy due either to peripheric causes or to the state of the blood, &c.) are purely artificial and based only on the knowledge of the cause. All kinds of epilepsy may cause attacks, exhibiting the same essential features. In idiopathic, as well as in any other kind of epilepsy, an irritation which may come from any of the reflecto-motor parts of the nervous system, goes to a great many other parts of the nervous system, producing in some an inhibition of action or of power of action, and in others a simple expenditure of the normal or morbidly accumulated nerve-force, or, together with an expenditure, an increased generation of force (dynamogeny<sup>1</sup>).

Two facts forcibly show how these various effects of an irritation are produced.

<sup>1</sup> The writer designates by that name just the contrary to inhibition. That action is the effect of a transformation of force due to an irritation, and in virtue of which there is a sudden or rapid production of force. A great many facts establish the dynamogenetic power of certain parts of the nervous system over other parts of that system and over contractile tissues. See his article 'Dynamogénie,' in the *Diction. Encyclop. des Sciences Médicales*.

(1) Under the influence of a very slight irritation—that of a superficial prick of the medulla oblongata, close by the *nib of the calamus*—the brain may be suddenly and (so far as the writer knows) irrevocably inhibited, so that all the powers and functions of that organ disappear, while, on the contrary, the spinal cord, the nerves, and the muscles gain immensely in power: they are *dynamogenised*. The loss of cerebral activity is not due to a diminution or a cessation of circulation in the brain, as, on the one hand, the heart, for a time, shows no great weakness, although breathing is stopped; and, on the other hand, the experiment succeeds although the cerebral blood-vessels are dilated owing to the previous extirpation of the two superior cervical ganglia.

(2) The other *fact* shows the simultaneous production of convulsions with inhibition and dynamogeny. Instead of pricking the medulla oblongata, that organ is suddenly crushed, and then it is found, first, that the powers of the cervical and of a part of the dorsal spinal cord are inhibited, sometimes so completely that they can be galvanised without producing any muscular action; secondly, that, for a longer time than in death by asphyxia, either tonic or clonic convulsions alone, or tonic followed by clonic muscular contractions, take place in the hind limbs; and, thirdly, that the power of that part of the spinal cord giving rise to convulsions is considerably increased, as shown not only by their violence and duration, notwithstanding the cessation of circulation, but also by the fact that reflex actions can continue to exist after convulsions have ceased.

The first of these facts clearly proves that one and the same cause—a very slight irritation in a certain part of the nervous centres—can change at once and everywhere the dynamical condition of the nervous and muscular tissues, inhibiting all the powers of the brain and increasing considerably the powers of the spinal cord, of its nerves, and of all muscles.

The second fact positively shows that an irritation of a certain part of the nervous centres can give rise simultaneously to three radically different effects—an inhibition; a production of nerve-force; convulsions due to an expenditure of nerve-force.

V. These facts throw a flood of light on the phenomena of epilepsy. First, they clearly show that it is by an act of inhibition that the loss of consciousness takes place. Secondly, they lead to the conclusion that convulsions do not require the pre-existence of a great quantity of nerve-force in any part of the nervous centres, and that they can take place, with great violence and last a long time, from irritations which need not be very great. The supposition that epileptiform fits depend on a sudden discharge of

previously accumulated nerve-force is no longer necessary.

VI. The lesions found in many parts of the brain in epileptic patients do not show the *seat* of epilepsy—they only have one or the other of the three following significations: First, they are places of irritation generating that neurosis in the same way as peripheric lesions in the skin, in mucous membranes, in nerves, &c., produce it. Second, they may be mere co-existing alterations, having no influence over the epileptic affection. Third, they may be, and very often are, effects of the changes in circulation, in the state of the blood, and in cerebral nutrition, during fits. The alterations of the medulla oblongata, described by Schröder van der Kolk, and more completely by Ch. Bouchard, are certainly, as pointed out by this last observer, effects of fits, but able, however, at certain stages of their development to have a share in some of the convulsive phenomena. The last effort recently made by Dr. Chaslin to establish that in idiopathic epilepsy there is a constant lesion, has failed like all others. That lesion, consisting in the existence of a diffuse sclerosis located chiefly in the grey matter, is so little the essential organic cerebral cause of that form of *morbus comitialis*, that Féré, in a case of cure of that affection, found that the brain was the seat of the cortical sclerosis, besides having an induration of the two cornua Ammonis.

VII. One only of the supposed seats of epilepsy in the brain deserves some attention. It is that part which is the most frequently found diseased in cases of unilateral epileptiform convulsions, whether Jacksonian in character or not—the so-called motor zone. That part is also very often diseased in cases of general epileptiform convulsions, and, not rarely, besides, in cases of apparently pure idiopathic epilepsy. This frequency of lesion of the so-called motor centres, in epileptic cases, may as well be due to the fact that an irritation starting from that place has given rise in other parts of the nervous centres to the morbid state in which epilepsy consists, as due to the fact that this peculiar morbid condition is really located there. In other words, a lesion of the cortex cerebri along the Rolandic fissure, like that of a nerve anywhere, may be only the location of an irritative cause and not the seat of this neurosis.

Many facts observed in animals and in man show that this supposition is the correct one. Experiments on dogs have shown to the writer that every part of the motor tract in the encephalon, after the production of an epileptic attack by the galvanisation of the so-called motor centres, can, on galvanic irritation, give rise to an identical convulsive seizure. They have also established the fact that it is on the motor cells of the base of the brain and of the spinal cord that the

irritation of the cortex cerebri acts, in producing, first, the morbid state constituting epilepsy, and afterwards genuine epileptic attacks.

VIII. What is proved for dogs is, at least, extremely probable for man. Clinical facts show that most frequently any kind of lesion of the so-called motor centres or of the neighbouring frontal convolutions<sup>1</sup> has given origin either to genuine and complete epileptic fits, or to the greatest variety of epileptiform manifestations. This has led to the erroneous conclusion that epilepsy has its seat in certain cortical parts of the brain. It can be shown that all parts of the cerebrum, of the cerebellum, of the base of the brain, and also the cerebral meninges, the spinal cord, and the centripetal nerves, can produce epilepsy. On the other hand, irritative lesions are known to have existed, in many cases, in one or another part of the frontal or parietal lobes without the appearance of epilepsy.

When any kind or form of that affection appears under the influence of a disease or of an injury to the cortex cerebri in the parts looked upon as its real location, the altered tissues, as the following facts well show, may be only the seat of an irritation acting on other parts of the nervous centres, so as to give rise to epilepsy and to its manifestations. This view is proved by the facts—1st, that when this neurosis is due to a worm in the bowels, it can be cured by the expulsion of the irritating cause; 2nd, that when it depends on a neuroma, or neuritis, it can be cured by the section of a nerve between the diseased peripheric part and the nervous centres; 3rd, that when caused by some pathological alteration of a cerebral convulsion, it can be cured by the excision of the diseased part. In all those cases there is a cure, not because the seat of this convulsive affection is separated from the nervous centres, but because the irritating cause is suppressed.

Sometimes, as is well known, epilepsy will continue after the expulsion of a worm, the section of a nerve, and the excision of a diseased convulsion, or the opening of a cerebral abscess. In the first place, the irritative cause may be only partly suppressed by those means; in the second place, as said already, the morbid state in which epilepsy consists may exist in other parts of the nervous system than those where the irritative causes are located. That morbid condition may persist, remaining able, under the influence of other irritations than those

<sup>1</sup> Dr. J. Hughlings Jackson, in his late remarkable 'Lumleian Lectures,' has put forward the supposition that the seat of 'complete or genuine' epilepsy is in the prefrontal lobes. Against this supposition the writer will only say that all the characteristics of this affection have existed when these lobes were either absolutely normal or completely destroyed.

which acted previously, to give rise to seizures.

IX. Together with the conclusions flowing from the facts and arguments above discussed, the writer will give some others, the grounds for which lack of space does not permit him to mention:—

1. Epilepsy is a reflex neurosis even when positively allied with an organic lesion of the brain. Its only constant feature is an increase of the reflex excitability of a number of nerve-cells located in various parts of the cerebro-spinal centres. That hyper-excitability is generally, but not necessarily, greater at the time of an impending fit.

2. No distinction can be made between the kinds of epilepsy, with predominances either of considerable disturbance of the mental functions or of the higher senses, or of convulsive movements, or of any symptom. The greatest variety of epileptiform manifestations can arise from a similar lesion in any part of the brain or elsewhere.

3. Some parts of the nervous centres are always ready to cause, rapidly but not immediately, all or some of the phenomena of epilepsy, under the influence of an irritation, and especially a sudden one, proceeding from any central or peripheric part of the incito-motor nervous system. Two successive and absolutely distinct actions take place then: the first is a morbid change in the properties of a number of cells of the nervous centres—change according to which epilepsy or an epileptiform affection is generated; the second is a reaction from those cells bringing outwardly the manifestations of the special kind of the neurosis produced.

4. All the manifestations of genuine epilepsy, even in its worst and inherited form, in certain animals, can take place after the destruction of the whole brain, including every part of the medulla oblongata.

5. The seat of epilepsy is not where an organic lesion or a traumatic injury is found, either in the brain proper, the cerebellum, or any other part of the nervous centres, nor in any nerve or viscus. All organic lesions are only foci of irritation, seats of causes. The true location of the morbid state constituting epilepsy or an epileptiform affection is in reflecto-motor nerve-cells in parts of the central nervous system varying extremely.

6. Attacks of epilepsy are not essentially due to an overflow of nerve-force accumulated anywhere. The same irritating cause which brings on an attack can produce nerve-force at the same time that it determines convulsions by discharges of that force.

DIAGNOSIS.—In most cases it is easy to distinguish epilepsy from the few affections which resemble it. Sometimes, however, difficulties exist. There is no essential difference between the attacks of eclampsia in women and children and attacks of epilepsy, except the

existence in eclampsia of a peripheric cause of irritation, which is likely to disappear. But those purely reflex epileptiform attacks in women and children are sometimes succeeded by genuine attacks of epilepsy. Changes in the nervous centres occur during the eclamptic attacks, and lay the foundation of persistent epilepsy, although the peripheric irritation, which was the first cause, has ceased to exist. It is sometimes, therefore, almost impossible, as regards children especially, to say if we have to deal with eclampsia or epilepsy. The same may be said of all kinds of attacks of loss of consciousness and convulsions due to a peripheric cause, whether we call the affection eclampsia or reflex epilepsy (*see* CONVULSIONS). The first cause in these cases may cease to exist without our discovering positively that it has disappeared, and still attacks may continue. A mistake is not dangerous, as the treatment will be very much the same, except that in purely reflex epilepsy we have to fight against the peripheric cause, besides making use of means against epilepsy itself.

As regards the known facts concerning the ætiology of epilepsy and hysteroid affections, it must be remembered: (1) That, instead of epilepsy, hysteria may appear in the descendants of epileptics; (2) that an organic disease of the brain can give rise to genuine hysteria or to mixed forms of hysteria and epilepsy; (3) that diseases of the womb or even of the ovaries can give origin to epilepsy, and diseases of the testicles to hysteria; (4) that traumatic causes, and especially injuries to nerves, can sometimes produce hysteria; (5) that syphilis, uræmia, worms in the bowels, lead poisoning, can give rise to hysteroid affections. Ætiology alone cannot, therefore, be decisive for the diagnosis between epilepsy and hysteria.

The aura hysterica and the epileptic aura are generally very different one from the other, but they may be quite similar. The writer has seen a case of idiopathic epilepsy in an adult male, in whom the *globus hystericus* was the warning of almost every attack. As regards other means of diagnosis, we will refer to the articles HYSTERIA and HYSTERO-EPILEPSY.

Epilepsia mitior (*petit mal*) sometimes cannot be recognised easily from syncope. In *petit mal*, however, the loss of consciousness is absolutely sudden; the eyes are fixed; almost always some muscles of the face are contracted; sometimes other muscles, in the neck and elsewhere, are also contracted; if the patient is standing he rarely falls, and if he is walking he may continue to do it. The attack is very short, and there may be no appearance of its having occurred, except that some mental disorder may follow it; the pulse may be diminished, but it never disappears altogether. Syncope differs from *petit mal* in all those characteristics.

It is not necessary to draw here the lines of diagnosis between idiopathic epilepsy and cerebral epilepsy. The characteristic features of this last affection have been described at length in several parts of this article.

PROGNOSIS.—Inherited epilepsy is very rarely cured. The writer can positively state, however, that it may be cured. Among other good cases of persistent cure, he has seen two extremely remarkable. The patients were first cousins, and had inherited the disease from a grandmother: one of them died from a fall while intoxicated, five years after his last attack of epilepsy; the other died from typhoid fever, seven years after his last attack. They had both been treated for about two years, in 1852 and 1853.

There is a very great difference as regards prognosis between pure idiopathic epilepsy and other forms of that neurosis. The possibility of cure is greater when some curable or amendable organic alteration exists as a cause of epilepsy. One form of this nervous affection—that which is due to some congestion or even a more serious alteration of the brain, consecutive to typhoid fever, scarlatina, or measles—is often much benefited by treatment, if not cured. Already, before the great progress in the treatment of epilepsy through surgical means, the writer looked upon epilepsy caused by disease of the brain—syphilitic or not—as much more curable than any of the forms of this neurosis, excepting, perhaps, that which is due to an easily removable peripheric irritation. Epilepsy beginning in childhood, from teething or a bowel complaint, and having lasted many years, is almost incurable.

TREATMENT.—*Abortion of the attack*.—A most important fact ought at first to be pointed out under this head: it is that, as every attack causes in the nervous centres changes which prepare other attacks, it is essential to produce, if possible, the abortion of attacks whenever warnings occur. The treatment to obtain such an abortion varies with the kind of warning. In cases in which a real aura exists many means can be employed with the greatest benefit. The writer long since showed that the old-fashioned mode of prevention of attacks, consisting in the application of a ligature round a limb, acts not as the Galenic doctrine supposed that it did—that is, by barring the way to something going up to the brain; but, on the contrary, in doing just the reverse—that is, by sending an irritation towards or rather to the nervous centres. The writer has also shown that the ligature need not be left applied, and that a greater success is obtained by tying suddenly a handkerchief or a band, and repeating this tying several times in succession, than by applying the ligature even very tightly and leaving it so. Besides, he has found: (1) that the

ligature can do good even when applied on another limb than that where the aura is felt, although it is more efficacious on the latter; and (2) that pinching or striking the skin, or irritating its nerves by heat, by cold, by galvanism, or by repeated pricks with a needle, will generally do as much good as the ligature.

In those cases in which an involuntary muscular contraction takes place before an attack—that is, before the loss of consciousness—one of the most efficient means to produce an abortion of the fit is to draw forcibly on the contracted muscles, so as to elongate them. For instance, in those cases in which the unconsciousness is preceded by a contraction of the muscles of the neck, which draws the chin towards one shoulder, turning forcibly and rapidly the head towards the opposite shoulder gives in most cases a very good chance of checking completely the tendency to the fit. In case of contraction of the flexor muscles of the forearm, forcible extension of the hand over the forearm may succeed in preventing the attack. A blow, pressure, or friction on parts where some muscles become rigid, may have the same favourable effect.

If there are disturbances of breathing among the premonitory symptoms, the inhalation of ether or chloroform may prove successful. In cases of laryngismus simular means, or the cauterisation of the fauces by a strong solution of nitrate of silver, has been found most useful by the writer. The use of anæsthetics as a means of warding off an attack is too much neglected. By the help of ether in inhalations the writer succeeded, with Mr. R. Dunn, in preventing an attack in a patient who had had a fracture of the arm in a previous seizure, and who used to have a fit regularly every week. A whole week was gained in that way. In some cases the recurrence of attacks has been warded off by giving chloroform or ether (by inhalation) to patients who had had the first of what would have been otherwise a series of many fits. There is, in cases in which a fit is expected, a considerable chance of preventing it by anæsthetics.

According to the kind of warning and to its seat, one means or another out of a very large number (some of which only shall be mentioned here) ought to be used. An emetic, a purgative, a stimulant, the immersion of the two hands in hot water, the application of a lump of ice to the back of the neck or between the shoulder-blades, the subcutaneous injection of a solution of  $\frac{1}{100}$  of a grain of sulphate of atropine with  $\frac{1}{2}$  of a grain of acetate of morphine, powdered *asarum* taken as snuff, a dose of 25 grains of hydrate of chloral, the inhalation of a small dose of nitrite of amyl, extremely rapid and ample voluntary respiratory movements for five or six minutes, jumping, running for at least

ten minutes, reading very loud and fast—such are some of the means which the writer has found to be the most successful.

In a number of cases, patients under the writer's care obtained abortion of an impending fit by making energetic movements. Sometimes, however, even when the warning allowed the performance of very powerful general movements for a long time, the fit came with its usual violence. These facts are in decided opposition to the view that attacks of epilepsy are the effects of discharges of accumulated nerve-force by the so-called motor centres, or by other parts of the brain. Just as the tension of vapour diminishes in a boiler when steam is let off, the amount of nerve-force should diminish as a necessary consequence of the expenditure taking place in voluntary movement.

The second point of importance about treatment is to try to discover a part of the body which can by irritation give rise to a premonitory symptom of an attack, or even to an attack itself. If such a part is discovered, counter-irritation of some kind is to be applied there. Our remarks must be confined to saying that hard pressure on certain parts of the head, the spine, the breast, the abdomen, or the limbs, has in a number of cases produced an attack or some symptoms of it. We have seen the passage of a galvanic current produce the same effect. In such cases a blister or other local application has done good in diminishing the violence or frequency of attacks, and even, in a few instances, helped notably to a cure.

It is a remarkable fact that, whether a sensory or muscular aura exists from some affection or injury in the neighbourhood of its seat in the periphery, or from an organic affection or a traumatic injury of the nervous centres, the best place of application of any means of abortion of an attack, or of cure of epilepsy, is the same—*i.e.* the skin near the seat of the aura, or along the passage of nerves going to that seat. If a place, which is not connected with an aura, is found to be capable under an irritation of giving rise to a fit, there also is the best situation for the application of counter-irritants and other means of treatment against the epileptic affection. One of the most powerful means of counter-irritation, in all cases like the above, is a circular blister to be applied all round a finger, a toe, or an arm or leg. This means, used also with benefit by Dr. Buzzard, has led him to find that sometimes the aura, under the influence of a circular blister, disappears from the limb so treated, and is transferred to homologous places of the other side. In a case of epilepsy of Récamier's, a sensory aura changed place a great many times, and each time after an application of a small blister. The aura

so pursued disappeared, and the patient was cured.

*Treatment during the attack.*—The best plan in most cases of epilepsy is simply to save the patient from the danger of striking anything which might cause a bruise; to loosen his clothing, cravat, &c., so as to give freedom to respiratory movements; to wash the face with cold water if it become covered with perspiration; and at last to turn the head and face at the end of the fit, so as to prevent the falling back of the tongue on the glottis, and even to draw forward the tongue if there is deep stertorous or comatose breathing. There is, however, one means of treatment which has certainly proved sometimes successful in curtailing an attack even in so-called idiopathic epilepsy, although it is more powerful in partial epilepsy due to brain disease or to some peripheric irritation: this is pressure on the part of the neck where lie the carotid arteries. The idea was to lessen the amount of blood going to the brain. Whether obtaining that effect is really of service or not the writer cannot say, but, as often stated by him, it is not possible to press strongly over the carotid arteries without pressing also on the cervical sympathetic and on the nervi vagi. It is known that Augustus Waller and Czermak have ascertained that in man, as in the mammalians, pressure on the carotid artery acts sufficiently on that nerve to inhibit the heart more or less completely. This effect is certainly quite capable of curtailing a fit. The writer has shown also that such pressure can act on the nerve so as to modify favourably the condition of the respiratory centres, and he has proposed to employ pressure on both carotids and neighbouring nerves in those cases of epilepsy (and also of apoplexy) in which the heart beats very violently, while the respiratory muscles partake of the general convulsions.

*Treatment of epilepsy itself.*—The modes of treatment of the various forms of epilepsy which chiefly deserve to be noticed, must be divided into two classes, the internal and the external and surgical. We will first speak of internal means.

Against idiopathic epilepsy the most powerful means consists in the simultaneous use of some tonic remedy (such as strychnine or arsenic) be taken after meals; and of a mixture composed more or less like the following:—

R. Potassii iodidi ℥ij.  
Potassii bromidi ℥i.  
Ammonii bromidi ℥iij.  
Potassii bicarbonatis ℥j.  
Tinct. calumbæ ℥j.  
Aquæ destillatæ ℥v.

Of this solution four doses a day may be given to adults, three of one teaspoonful each before meals, and the fourth of three teaspoonfuls at bedtime, with as much water as desired. According to many circum-

stances the dose of one or another of the ingredients is to be changed. For example, if the *petit mal* exists alone, or co-exists with the complete epilepsy, the dose of the bromide of ammonium must be larger, and that of the other bromide diminished. If there is a weak pulse, carbonate of ammonium is to be substituted for the bicarbonate of potassium. In the writer's work on functional nervous affections all the rules relating to this mixture are given, and he will only say now that its use is considerably more beneficial than that of any of its ingredients alone, or any two of them. Two essential rules are to be followed when bromides are employed against epilepsy. The first is, that there ought to be no cessation whatever in the use of such remedies, as the whole benefit that may have been obtained may be lost at once after an interruption of even only a few days; the second is, that the treatment must be persevered with for at least two years after the date of the last attack. There is no evident harm in the great majority of cases from a prolonged use of a mixture like the above; a large number of patients have taken it for many years without any marked bad effect.

The writer has tried many other bromides than the two of this mixture. None has answered so well as these two. In a great many cases he has made use simultaneously of this mixture and of one or another of the many remedies which have been proposed for epilepsy. None of them has proved very useful except when there was some local affection which could be benefited by the added remedy. Such has been the case with atropine, ergotin, cannabis indica, digitalis, aconitine, cod-liver oil, &c.

In those cases in which the above mixture either did not produce a sufficiently good effect, or, still more, allowed of an increase of the convulsive neurosis or of *petit mal*, the use of atropine, of the ammoniated sulphate of copper, of borax, of the oxide or other salt of zinc, has frequently proved useful. It is not possible to say in what kind of cases one of these remedies is to be used rather than the others, except that zinc seems to be of better use when hysteria is more or less mixed up with epilepsy.

The writer has obtained a permanent cure of two cases of idiopathic epilepsy through the agency of nitrate of silver, without any discoloration of the skin. He employed a small dose ( $\frac{1}{8}$  of a grain three times a day), and stopped giving the medicine for eight or ten days after having had it used for three weeks. It required nearly a year for the complete cessation of the fits, and the use of the remedy was continued a few months after the last attack.

*Petit mal*, as well as complete epilepsy, can be treated advantageously with the above-mentioned mixture. Much benefit will some-

times be obtained in the treatment of this special neurosis by the addition of arsenic or of atropine.

It is hardly necessary to say that, when syphilis is the cause of epilepsy, the dose of the iodide of potassium in the prescription is to be notably increased (it must be at least a drachm a day), and also that frictions with the mercurial ointment are often to be resorted to. If epilepsy depend on some visceral affection, it is clear that the treatment should be directed against that affection. But if the liver is diseased from some influence of malaria, the sulphate of quinine should not be given, as it is almost always a bad remedy to employ in epilepsy, often more hurtful than useful. Arsenic should then be the remedy used for the sequelæ of fever and ague. If quinine must be employed in cases of clearly periodical epilepsy, the valerianate should be given.

The writer's experience shows that in most cases of epilepsy iron is harmful rather than useful. It is only in cases allied with or caused by chlorosis or considerable anæmia that the good effects of iron or manganese are often very marked. Still, the citrate of iron, although less powerful against a deficiency of blood-globules, may be used, because it is less apt to give rise to attacks than are most ferruginous preparations. Writers who disagree with these views (which are accepted by Dr. Hughlings Jackson) have lately tried to show that iron can always do some, if not much, good, and can do no harm; but they have, in support of their statements, given cases belonging rather to hysteroid affections than to epilepsy.

The writer has obtained no decided good effects from nitrite of amyl, antipyrin, picrotoxine, curara, or simulo.

It is important to state that, in cases of status epilepticus, the prompt and continued use of anæsthetics (ether, chloroform) may stop the tendency to the recurrence of fits. The condition of the tongue must then be watched carefully. If, as is usual, the fits are very violent, this organ falls over the larynx and increases the state of asphyxia, which contributes to the return of convulsions. The tongue is to be drawn forward, and any accumulation of frothy or bloody mucus in the throat must be wiped out. Anæsthetics have some power of curtailing, if not stopping at once, the tendency to a return of fits.

*External and surgical means.*—The notion that, if epilepsy depends on a peripheral cause which can be removed, it is right to employ surgical means, has often been acted upon, and with decided benefit. The number of cases is large in which a cause has been profitably suppressed by an operation or some other means. In a good many such cases, the section of a nerve or the extirpation of a foreign body or a tumour

has proved successful. Lately some cases of stretching of nerves, followed by cure or amelioration, have been published. A great deal is to be expected from counter-irritation. Ice applied on the bare skin, the actual cautery, or sedative applications on sores, may do much good.

As regards cases of idiopathic or cerebral epilepsy, all kinds of counter-irritation on the nape of the neck or at the level of the first and second dorsal vertebræ may prove useful, especially if there is considerable pain or heat in the head. When attacks are very violent and frequent, a decided amelioration may be obtained from croton-oil applications on a great part of the shaved scalp. Setons and issues very rarely do any good, and often weaken and irritate.

Among surgical means against epilepsy, two bold and somewhat strange operations have successively been proposed by an able surgeon, Dr. W. Alexander, of Liverpool: the one was supposed to act in producing anæmia in the base of the brain; the other, on the contrary, was to cause a vascular fulness. The first of these means consisted in the ligature of both vertebral arteries. Out of 36 cases there was a temporary cure or a persistent amelioration in 19 cases—certainly a very large proportion. Having given up this therapeutic means, Dr. Alexander formed the idea of taking away on the two sides the superior cervical ganglion of the sympathetic nerve, and obtained this remarkable result—that there was a cure or an improvement in 25 per cent. of the cases, while it is generally admitted that medical treatment gives about 7 per cent. of cure or improvement. The writer, notwithstanding the apparent superiority of this kind of treatment, would be quite indisposed to recommend it except after complete failure of all the best internal remedies.

Operations on the genital organs of epileptics of the two sexes are only to be resorted to in desperate cases.

Trephining against epilepsy, during a great part of this century, although employed indiscriminately, has nevertheless frequently proved useful. It is now, in appearance, used according to rational scientific principles—in reality sometimes quite faulty. Statistics show that, with the addition of very bold operations, it is not so frequently useful as it previously was. In other parts of this article (*Ætiology*; *Symptoms*) there are facts showing that recognition of the seat of a tumour or of some other organic disease of the brain is not always possible, and must in many cases be extremely difficult. Be that as it may, it is quite certain that not rarely after the laying bare of the dura mater or the cerebral convolutions, surgeons have been disappointed in not detecting an expected morbid state to which they attributed an existing epileptic affection. On the other

hand, however, they were, sometimes, agreeably surprised in finding that in such circumstances the affection disappeared. In 1857, after having given all the details of a case of the kind, furnished to him by Dr. van Buren, the writer in his work on Epilepsy put forward a view, very tersely expressed a few years ago by Dr. Gowers in the following sentence: 'It is possible that the measure (trephining) is sometimes beneficial as an energetic form of counter-irritation, but it is doubtful whether for this object its performance is justifiable.'

Knowing how powerful counter-irritation may be against epilepsy caused by a blow on the head or allied with some tenderness of a point of the scalp, the writer long ago proposed that, before resorting to trephining, the most energetic means of counter-irritation should be employed. Trials should be made of ice applied on the shaved and bare skin of the head twice a day for an hour each time, of the actual cautery, of blistering, of croton oil, and of a means which the writer (imitating Pouteau) used successfully in two cases, consisting in a deep crucial incision of the scalp and the pericranium (the cuts being of one inch and a quarter). It is possible that it was a more or less similar operation, and not the trephining, which was the means of success in the cases above mentioned.

When we read of cases of cure after the extirpation of bony spiculæ or of a mass of cicatricial tissue, of a tumour, or of a certain amount of the convolutions of the brain, it is impossible not to be struck with the resemblance of these facts to the cases of cure of epilepsy by the expulsion of worms from the bowels, or the removal of a neuroma or a foreign body pressing on a nerve, or of other causes of peripheric irritation. The analogy between the cerebral and the peripheric cases is very great: both are cases of reflex epilepsy. In both kinds of cases there may be a failure of the means used, owing, no doubt, to changes having occurred in the nervous centres which are able to give rise to attacks of epilepsy. In such cases the excision of the supposed centre of certain muscles may not be followed by a cessation of convulsions of those parts. So it was in the case of a boy spoken of by Dr. Ferrier, and who had been operated upon by Mr. V. Horsley.

Notwithstanding the diminution of risks due to antiseptics, great is still the proportion of deaths following, if not caused by, the operation of trephining, with the ablation of morbid parts of the brain, and sometimes, alas! of perfectly healthy-looking parts.

There is no doubt that surgeons are entitled, in certain cases, to employ trephining against epilepsy; but, for the reasons above briefly given, the writer thinks that,

before resorting to this operation, when there is no clear evidence that some morbid parts are to be removed or an abscess to be opened, or some necessity arising from a fracture, it would be wise to first exhaust all means of counter-irritation.

C. E. BROWN-SÉQUARD.

**EPILEPTIC INSANITY.**—SYNON.: Fr. *Folie épileptique*; Ger. *Epileptisches Irresein*.

**DEFINITION.**—Mental disorder which is the outcome of the epileptic neurosis, and which is generally, though not invariably, accompanied by motor epilepsy.

**ÆTIOLOGY.**—The statements in the article EPILEPSY may be taken generally as applicable to epileptic insanity. But an exception must be made in regard to what is said concerning sympathetic epilepsy, the insanity described here being associated only with epilepsy of cerebral origin.

**PATHOLOGY.**—The structural changes associated with epileptic insanity have their seat in the cerebral cortex, and involve an altered nutrition of certain of the nerve-cells. This altered nutrition is usually due to idiopathic degeneration; but it may also be due to morbid growths or other irritative lesions in neighbouring parts of the brain. It seems probable that functional disturbance of the cells in the higher centres or psychic area may be excited by radiation from the motor area in which an epileptic discharge originates; but in most cases there can be little doubt that the cells in the psychic area are themselves the subject of structural change. In some cases, indeed, the psychic centres are the first affected, and the discharges may be at least for a time limited to these centres. In such cases the discharges are manifested by loss of consciousness, hallucinations, or outbursts of mania unaccompanied by convulsions. The structural change chiefly occurs in the small irregularly shaped nerve-cells which are found in the second cortical layer. Bevan Lewis regards as of a highly characteristic nature a fatty degeneration of the nuclei of these cells, which goes on to vacuolation, and ends in complete disintegration of the cells. He describes similar changes as usually affecting to some extent the other layers of the cortex. This form of degeneration is not, however, as Bevan Lewis himself shows, peculiar to epilepsy; and other observers, though using Bevan Lewis's own method of examination, have failed to find it in some cases of epilepsy. When a patient dies in a fit, there is usually found intense venous engorgement with sometimes punctiform hæmorrhages in all the viscera, including the brain. This condition has important pathological bearings; but it is post-epileptic in its nature, and is properly regarded, not as the cause, but as a result of the epileptic seizure.

DESCRIPTION.—It is necessary to consider separately three aspects of the unsoundness of mind which is associated with epilepsy, according as it appears (1) as arrested or impeded mental development—*epileptic idiocy* and *epileptic imbecility*; (2) as progressive mental degeneration—*chronic epileptic insanity*; and (3) as transient mental disorder—*acute epileptic insanity* or *epileptic mania*. These three conditions are to be regarded as different phases and not as different kinds of epileptic insanity. They are intimately connected with one another, and occasionally they may all be illustrated in the progress of a single case. Thus epilepsy supervening during infancy or youth may so retard mental development as to produce imbecility; the subsequent periodical recurrence of epileptic fits during adult life may gradually pervert and deprave the already imperfect intelligence, causing it to pass through a phase characterised by emotional disorder, hallucinations, and delusions, and ending in the hebetude of complete dementia; this progress may occupy many years, and it may be interrupted by intercurrent outbursts of acute maniacal excitement. Though it is necessary, therefore, for the purpose of description to deal with each of the phases separately, their interdependence must not be overlooked.

1. **Epileptic Idiocy and Epileptic Imbecility.**—These terms are used to indicate different degrees of the same affection—a more or less complete arrest of mental development due to epilepsy. Those individuals in whom epilepsy supervenes in infancy, where there is no development of mind, or very little, are called idiots. Those in whom epilepsy commences after substantial progress has been made in mental growth, or in whom the epileptic seizures, though appearing early, do not recur frequently, and where there is considerable though defective mental development, are called imbeciles. The effect of the fits upon the mental condition of children differs greatly in different cases. The fits are usually followed by more or less mental retrogression. In many cases after a fit, and especially after a series of fits, the patients fall into a state of prostration and stupor of some duration. The educational training of the epileptic imbecile is seriously embarrassed by the occurrence of such attacks. A great part of what has previously been learnt seems to be wiped out, and requires to be learnt over again. In cases where the fits cease the evolution of the intellect may resume its course, but the mental organisation always remains damaged. It is estimated that about one-third of the total number of cases of idiocy are due to epilepsy.

2. **Chronic Epileptic Insanity.**—In a large number of epileptics, estimated by Russell Reynolds at about one-third of the total number, the mental condition is not affected to such a degree as to be recognised

as abnormal; and in a small number of cases the disorder is limited to a few brief attacks, sometimes to a single attack, of maniacal excitement. In about two-thirds of the cases there is an appreciable mental enfeeblement which gradually increases so long as the fits continue to recur, in some cases never going farther than a peculiar emotional mobility and weakness of memory, and in others passing on to profound dementia. This progressive mental degeneration, though varying greatly in degree, is very uniform in type, and it is important to be able to recognise it. In the mildest cases there are usually to be detected lapses of memory, fits of absent-mindedness, and transient confusions of thought; and there is always more or less instability of mood and morbid irritability. The instability is the most characteristic mental feature of the epileptic. At one time he will be gloomy, despairing, conscious of his mental enfeeblement, and lamenting its hopeless nature; at another time he will exhibit a surprising self-satisfaction, hopefulness, and confidence. Many epileptics are liable to fits of intensely passionate anger, occurring without apparent cause. The changes of mood often take place with a startling suddenness which is important as a diagnostic indication. In the fully developed chronic insanity of the epileptic the variability of the mental condition may show itself in the intellectual as well as in the emotional state. A patient who usually exhibits confusion of thought, weak memory, and little power of attention may suddenly awake to a state of great mental activity, and show remarkable clearness and rapidity of thought, vivid memory, and great power of concentration. A common condition is to be habitually quarrelsome, argumentative, fond of teasing, insolent in demeanour, and given to capricious cruelty; yet such patients will sometimes be found marvellously sweet in disposition, benevolent, affectionate, and considerate. In the advanced stages of the disorder the moral nature is generally deeply degraded, as shown in repulsive obsequiousness of demeanour, low cunning, treachery, and cruelty. The intellectual condition also passes through stages of degradation. Delusions of being injured by other persons fill the mind, and visual and auditory hallucinations occur. When these are present the patient, with his tendency to impulsive passion, is dangerous to persons near him. The last stage is marked by complete loss of moral sense and mental capacity. Nothing remains but the lower instincts in their most degraded form; and this is accompanied by a physical debasement which accords only too well with the mental condition.

3. **Acute Epileptic Insanity—Epileptic Mania.**—The term 'epileptic mania' is used to denote a peculiar automatic form of acute mania which sometimes follows epileptic seizures, and more rarely occurs in

persons with the epileptic neurosis who have never had a convulsive attack—or at least who have not been known to have one. There is generally some transient mental perturbation preceding or following a convulsive seizure, which does not attain the intensity of mania, but which may be fitly alluded to here. The pre-paroxysmal phase of these perturbations may last for a few hours or a few days. They consist in a development of conditions which have been already described as characteristic of the early stage of chronic epileptic insanity. Sometimes there is morbid irritability, depression, or exaltation, sometimes confusion of thought or loss of memory. Immediately before the occurrence of a fit there is often some special idea which rivets the attention, the recollection of some particular scene, or a special hallucination such as a flame, a red colour, a spectre, or a peculiar odour. When there is a particular idea, or an hallucination, it is usually the same which recurs at each seizure, and it generally has some relation to the circumstances in which the first fit occurred. After the convulsive fit has passed off, there is frequently a short period of confusion of thought, and lethargy. The condition known as epileptic mania is an outburst of maniacal excitement lasting from a few hours to several days. The general features which are distinctive of these attacks are the suddenness of their onset, the violence and abrupt rapidity of the acts of the patients, the painful and appalling nature of the ideas and hallucinations from which they suffer, the suddenness as well as the completeness of the return to sanity, and the entire, or nearly entire, forgetfulness of what has happened during the course of the attacks. During an attack the impulsive acts are often of a homicidal or suicidal character, and this makes epileptic mania one of the most dangerous of all kinds of insanity. Sometimes the attack is characterised by furious maniacal excitement during its whole course, but there are also cases in which there is an apparent calmness of conduct. In a typical case of this kind the patient is irritable, suffers from a vague terror, seems impelled by a force, which he feels irresistible, to commit acts without conscious purpose. In this state the patients will walk long distances without object, steal or destroy articles in an unaccountable way, and will commit homicide or suicide with apparent deliberation. They seem insensible to everything which does not fall in with their dominant idea or impulse. This automatic action is a special characteristic of epileptic mania, both in the cases where there is violent excitement, and in those where there is an appearance of deliberate co-ordination of thought and act. The patients are as if in a waking dream; and when they awake suddenly to rational consciousness, they feel as if they had passed through a dream which they dimly conceive

to have been of a distressing and frightful nature, but of whose details they have no recollection, or only a very vague one.

The relation of the mental disorder to the convulsive seizures is concisely given in the following sentences. When the fits are frequent, and continue through a course of years, they are generally associated with chronic epileptic insanity, though there are exceptional cases in which the mind is not seriously affected. Where the fits are frequent, and are of the character of *petit mal*, the mental degeneration is usually more rapid and complete than where the motor symptoms are more severe, as in the *grand mal*. The calmer type of epileptic mania, called by Falret *petit mal intellectuel*, is most frequently associated with fits of the character of *petit mal* and with nocturnal fits; while the violent excitement, called by Falret *grand mal intellectuel*, is most frequently associated with the severe motor fits. Epileptic mania is most frequent after a fit or a series of fits, is less frequent before a fit, and least frequent in the intervening periods; it is specially apt to occur after a recrudescence of fits following a long period of freedom from them. It is also apt to occur after a rapid succession of abortive fits. It is rare in the first stages of epilepsy, most frequent in the middle stage, and rare after dementia has begun.

TREATMENT.—In the treatment of epileptic insanity everything which is useful in the treatment of epilepsy is to be included (*see EPILEPSY*). The bromides are the most important remedies, especially bromide of potassium. It should be given persistently in doses just short of producing bromism, combined with small doses of arsenic. It may be given for years if necessary. When syphilis is present, the bromide should be combined with the iodide. When pre-paroxysmal symptoms are observed, 20 grains of chloral hydrate should be given and the patient put to bed. The same treatment is useful after a fit; and it may also arrest a fit, or series of fits, or ward off an attack of epileptic mania. Constipation and overloading of the stomach with food should be carefully avoided. There should be complete abstinence from alcohol; it is apt to bring on fits and also mania.

MEDICO-LEGAL RELATIONS.—Where responsibility for acts committed in what seems to have been an attack of epileptic mania is in question, the whole character of the mental symptoms and the evidence of other epileptic conditions must be kept in view. The difficult cases are those in which there has been no violent excitement, and when the conduct has had the character of the calmer type of epileptic mania. Here it is important to bring clearly out the automatic character of the conduct. But the most important point is the existence of the fits. It may happen that the fits have not been recognised though

they were really present. Nocturnal fits are the most likely to escape recognition. It must not be forgotten that they may have occurred without the knowledge of the patient himself. Careful inquiry should therefore be made for signs of their occurrence, such as biting of the tongue, of the lips, or of the cheek; spots of blood on the pillow; gathering of froth about the mouth on waking; unconscious emission of urine; peculiar fits of snoring; or the occurrence of numerous small ecchymoses under the skin of the neck or forehead, the last being a sign the importance of which is strongly insisted on by Trousseau. When no convulsive fits can be ascertained, evidence of vertigo, or of brief losses of consciousness occurring periodically or in series, should be looked for. If in the opinion of a medical witness an act of violence has been the result of epileptic insanity, it is his duty to show that not merely the act itself, but also the conduct and condition of the accused otherwise, are symptomatic of the epileptic condition.

JOHN SIBBALD.

**EPILEPTIFORM }.—Partaking of the**  
**EPILEPTOID }**  
characters of epilepsy; terms generally applied to convulsions. See CONVULSIONS.

**EPIPHORA** (*ἐπί*, upon; and *φέρω*, I carry).—A flow of tears so persistent that they run down the cheek, due either to obstruction of the lacrymal duct or to excessive secretion. See LACRYMAL APPARATUS, Diseases of.

**EPIPHYTA** (*ἐπί*, upon; and *φυτόν*, a plant).—These are the plant-like organisms found on the skin and its appendages, or on mucous surfaces, the so-called *vegetable-parasites*, originating certain diseases, such as the various forms of tinea and thrush. The more important of them are the achorion, trichophyton, and microsporon. The achorion Schönleinii is the vegetable fungus which constitutes the mass of the crusts of favus, and belongs to the group of oidia. The trichophyton is the dermatophyte of tinea and sycosis, and is found in the substance of the hair as well as in the epidermis. The microsporon, termed epidermophyton by Bazin, is the parasitic fungus of pityriasis versicolor. Both the latter are members of the group of torulacæ. See EPIPHYTIC SKIN-DISEASES; and APHTHÆ.

ERASMUS WILSON.

**EPIPHYTIC SKIN-DISEASES.**—**SYNON.:** Tineæ; Dermato-mycoses or Dermato-phytoses; Ringworms; Fr. *Trichophytes* (Besnier); *Teignes*; Ger. *Flechte*.

**DEFINITION.**—An *epiphyte* is a living vegetable organism which grows in the superficial parts of the skin or mucous membrane of another organism, and is parasitic—i.e. lives at the expense of its host.

**CLASSIFICATION.**—The vegetable parasites are all fungi and belong to the subdivisions Schizomycetes (bacteria), Blastomycetes (yeasts), and Hyphomycetes (moulds). In addition to the pathogenic microbes of anthrax, glanders, erysipelas, leprosy, tuberculosis, &c., which may occur in the skin in association with these diseases, there exists under normal conditions a number of micro-organisms amongst the scales of the skin and its appendages, in nature between saprophytes and genuine parasites. There is a growing tendency to assume that, under certain conditions, this 'dermatological flora' may possess pathogenic properties. There may also be found from time to time accidental organisms of various kinds, and these are the pyogenic microbes. A parasitic origin has been ascribed to alopecia areata, but not proved; and the ætiological connexion of certain organisms found in furuncles, oriental sore, and impetigo contagiosa, &c., is still unsettled. Lastly, there are the bacteria of bromidrosis and red sweat, and the organisms associated with certain hair conditions, such as tinea nodosa, piedra, and forms of sycosis.

Apart from all such, however, there is the distinct group of Hyphomycetes, achlorophyllous thallophytes, living only on organic carbon compounds and needing oxygen, which constitutes the long-established class of true epiphytic diseases. The group is composed thus:—

1. *Tinea favosa* or *favus*, caused by the *Achorion*, discovered by Schönlein. The phases occurring in the scalp, beard, non-hairy parts, and nails may be specially noted.
  2. *Tinea trichophytina* or *ringworm*, caused by the *Trichophyton tonsurans* of Gruby and Malmsten. Here also the phases occurring in the scalp, beard, non-hairy parts, and nails have special characteristics.
  3. *Tinea imbricata* or *Tokelau ringworm*, a special (?) form found in Polynesia, and the Malay and Indian Archipelagos.
  4. *Tinea versicolor* or *chromophytosis*, caused by the *Microsporon furfur* of Eichstedt.
  5. *Erythrasma*, caused by the *Microsporon minutissimum* of Burckhardt.
- To this list are usually added *mycetoma* or the fungus-disease of India, due to the *Chionophye Carteri*; and an obscure disease of Mexico and parts of Central America called *pinta*.

This group of the Hyphomycetes, whose natural history is even yet not fully known, stands apart by itself, but its members are most nearly allied to the Mucorinæ. The difficulty of determining their affinities and classification has given rise to much controversy, now almost subsided. Increased knowledge of their morphology, direct experiment, and successful pure cultures have established that these dermatomycoses are

not due to polymorphic forms of some mould, such as *Penicillium*, *Aspergillus*, *Mucor*, &c., but are distinct species, with different vegetations, growing in a constant and determined form, with different behaviour under attempted cultivation, and always giving rise to similar objective symptoms. *Tinea trichophytina*, *favosa*, and *versicolor* cannot give rise to one another, but breed true. These dermatomycoses are contagious, and are inoculated from person to person and from animals. Their fungi have no sporangia, but consist of spores and simple or branched, jointed or unjointed, filaments or tubes, which are either mycelial (vegetative) or spore-bearing. The spores become isolated, or are arranged in moniliform threads or in masses. Balzer says, 'Everything is derived from the spore, which by elongation forms a tube or filament of mycelium; in the interior of this tube the substance of the nucleus (*protoplasm*) buds, sends out lateral processes and segments, so as to form the *spore-bearing tube*; when, later on, segmentation of the sheath occurs in its turn and imprisons the segments of the central substance, new spores are thus formed and will evolve, in their turn, in a similar manner.'

**DESCRIPTION.**—To examine the fungus, some epidermic scales should be scraped, or a hair placed on a slide, and soaked for a time in 20 to 40 per cent. soda, potash, or ammonia solution or in acetic acid. Then the specimen should be gently pressed out by the cover-glass to ensure proper focussing, and examined by a microscopic power of 300 or more diameters. If there is much fat present, the material must be previously soaked in ether. For more accurate and delicate examination, coloration of the specimen is necessary with methyl violet, eosin, or iodine. The erythrasma fungus needs high powers and staining. It is often impossible to name with certainty isolated spores or even filaments of these epiphytes, but when seen in bulk and in connexion with the clinical symptoms, there is rarely any difficulty. Unfortunately there are no elective stains to differentiate them. The abundant *Microsporon minutissimum* is so minute and slender as to be unmistakable. *M. furfur* also is very characteristic, with its roe-like masses of large uniform spores, and its short, much curved pieces of mycelium. The *Achorion* and *Trichophyton* are much more difficult to distinguish apart from cultures, and they differ from the other two epiphytes in attacking the hairs, though *achorion* does so to a much less extent than *trichophyton*. Kaposi says *achorion* displays a predominance of conidia of very variable size and shape, a comparatively short and remarkably jointed mycelium, a scarcity of smooth-bordered tubes, and a facility for breaking up into single cells; *trichophyton* less numerous, smaller and more uniform conidia, and more

tenacious, branched, and smooth-bordered mycelium. In the hair and nails, however, *trichophyton* forms conidia with the greatest freedom.

**ANATOMICAL SEAT.**—These dermatomycoses flourish in the epidermic tissue—*i.e.* the epidermis, hairs, and nails. We know little of many of the conditions of the soil favourable or otherwise to their growth. *Achorion* and *trichophyton* prefer the skin of the young and such as grows fine hair. These fungi are more likely to attack and flourish in uncared-for children, and hence the prevalent idea that ill-health or dirt are essential factors. A certain degree and combination of moisture and temperature are favourable, as exemplified by the affection of calves after being shut up in winter quarters, and by tropical ringworm.

**EFFECTS.**—The effects which epiphytes produce are, firstly, to mechanically dissociate and thus destroy the epidermic cells, on the nitrogenous products of which they live; and, secondly, to cause local inflammation, chiefly in all probability by the formation of irritating chemical substances. The degree of inflammation excited varies for each fungus and with different individuals; and it is difficult to determine the relative parts played by individual susceptibility, and the powers of irritation possessed by the fungus under the different conditions of its source of origin, the character of the nutrient medium, &c. The inflammation may be evidenced only by hyperæmia and desquamation, or by exudation and the formation of papules, vesicles, pustules, &c. As the fungus tends to grow equally in all directions, a rounded area of inflammation is formed, which subsides in the older central parts, so that a *ringed eruption* is commonly produced.

The general health is not perceptibly affected by any absorption of the products of fungus-growth, nor is there evidence of any auto-vaccination preserving from a second attack.

These dermatomycoses are inoculable from human beings and some lower animals directly, and by means of infected caps, towels, brushes, razors, clothes, &c. Their course is usually very chronic, but the soil may become exhausted and unfavourable.

**DIAGNOSIS.**—The diagnosis, when the clinical symptoms are well-marked, is clear; but scientifically, and even practically at certain stages, it is necessary to search microscopically for the fungus.

**PROGNOSIS AND TREATMENT.**—The *prognosis* depends on the site affected and the nature of the fungus; but the dermatomycoses are all amenable to *treatment* by parasiticides and the mechanical removal of the fungus. Great inconvenience and annoyance, however, are occasioned, and sometimes disfigurement. See *TINEA TONSURANS*; *TINEA VERSICOLOR*; and *FAVUS*.

**EPIPLOITIS** (*ἐπίπλοον*, the omentum). Inflammation of the epiploon or great omentum. See PERITONEUM, Diseases of.

**EPISPADIAS** (*ἐπί*, upon; and *σπάω*, I tear).—A malformation of the penis, in which the urethra opens on its upper surface. See PENIS, Diseases of.

**EPISPASTICS** (*ἐπί*, upon; and *σπάω*, I draw).—Substances which, when applied to the skin, are capable of producing a blister. See COUNTER-IRRITANTS.

**EPISTAXIS** (*ἐπί*, upon; and *στάζω*, I drop).—SYNON.: Fr. *Épistaxis*; Ger. *Nasenbluten*.

DEFINITION.—Epistaxis signifies a bleeding from the nose.

ÆTIOLGY.—Epistaxis is either *traumatic* or *idiopathic*.

The *traumatic* form may be occasioned by a blow, by violent sneezing, by snuffing up irritating substances, or by direct violence; but in these cases there frequently appear to be general or local *predisposing* causes to account for the readiness with which it occurs, such as a hæmorrhagic diathesis, an inflammatory or congestive hyperæmia, or some ulceration of the mucous membrane.

The *idiopathic* form of epistaxis frequently occurs in children, particularly boys, just before or about the age of puberty, and in girls as a form of vicarious menstruation. Epistaxis may be one of the forms of bleeding in persons of hæmorrhagic diathesis, in which case it is a source of anxiety and difficulty. Occurring in advanced life, it may be indicative of over-tension or obstruction of the cerebral venous system from chronic Bright's or cardiac disease; and the blood which flows is then often venous in appearance. Occasionally it occurs as a spontaneous relief to determination of blood to the head, in which form the blood generally proceeds from one nostril only. In other instances epistaxis is connected with serious disorder of the blood, as in the specific fevers. Thus it is often associated from the outset with remittent, enteric, typhus, or scarlet fever, and is indeed regarded in some degree as pathognomonic of enteric fever. It may also attend scurvy, purpura hæmorrhagica, splenic disease, pyæmia, and erysipelas, being a consequence of the septic condition.

In its passive form, epistaxis may be associated with organic disease of the heart, pleurisy, emphysema; or with ascites or ovarian dropsy, on account of pressure on the diaphragm inducing a stasis of the venous circulation. It may occur spontaneously from exposure either to great cold or great heat, or a sudden change from cold to heat, or from the diminution of atmospheric pressure, as in going up high mountains.

SYMPTOMS.—Hæmorrhage from the nose is too familiar to demand description in this

place. The flow of blood may be either continuous or drop by drop. As a rule, the escape of blood is from one nostril, bleeding from both being rare. It may last a very short time, or for some hours, and in severe instances for days, causing syncope, or even being attended with fatal results. It is at times met with as occurring periodically.

DIAGNOSIS.—Epistaxis must not be confounded with hæmoptysis, as may happen if the epistaxis takes place posteriorly, and the blood passes into the mouth.

TREATMENT.—When epistaxis is obviously a salutary process, as it undoubtedly is in a good many instances, it subsides spontaneously; where it occurs frequently and severely, recourse must be had to mechanical, cutaneous, or internal remedies. The local application of cold, in the form of cold-water or iced compresses to the nose, neck, or forehead is most useful, acting as these agents do either directly or by inducing a reflex effect on the vaso-motor nerves. Simple pressure upon the nostril, or upon the septum nasi, by compressing the bleeding nostril with the finger of the opposite hand, while the arm of the affected side is raised above the head, is the most readily practicable and effectual of all measures. The application of mustard over the stomach or upon the ankles is sometimes successful. When simple means fail, astringents, either in the form of solution or powders, may be injected into the cavities, or applied on plugs of lint or cotton-wool; such as alum, acetate of lead, the salts of iron, or gallic or tannic acid.

Internally, the frequent administration of saline purgatives, tincture of perchloride of iron, turpentine, bromide of potassium, belladonna and quinine, ergotin (subcutaneously), sulphuric acid, or acetate of lead, may be necessary in cases of periodic attacks.

In very severe cases the operation of plugging the nares, and thereby favouring the formation of a clot, must be resorted to; and the most ready and easiest method is by the employment of Bellocoq's sound, or, more properly, cannula. If, however, this instrument be not at hand, a catheter or an eyed probe should be threaded with a stout silk or hemp ligature, and pushed along the floor of the nose until it protrudes beyond the velum palati; one end of the thread should now be pulled out of the mouth by the fingers or forceps, and a roll of lint or a piece of sponge tied to it, and then pushed up behind the velum. The catheter and the attached thread being now withdrawn through the nostril, the plug is pulled forcibly against the posterior nares, and by the pressure exerted the hæmorrhage can generally be arrested. The intra-nasal plug is invaluable. It consists of a thin indiarubber bag, connected with a tube provided with a stopcock. The bag is passed empty along the floor of the nose into the nasal fossæ, and then blown up or filled

with water. Transfusion is indicated in very severe cases, where there is danger of delay. The strictest antiseptic precautions should be used in 'plugging'—such as puffing with iodoform, or syringing with the various antiseptics, as it not infrequently happens that the condition known as *ozæna* commences after severe cases of epistaxis.

EDWARD BELLAMY.

**EPISTHOTONOS** (*ἐπισθεν*, forwards; and *τείνω*, I extend).—A synonym for *emprosthotos*. See *EMPROSTHOTONOS*.

**EPITHELIOMA** (*ἐπί*, upon; and *θηλή*, the nipple (the word 'epithelium' being at first used for the tissue covering the nipple); and *oma*, a termination indicating a tumour).—**SYNON.**: Epithelial Cancer; Canceroid; Fr. *Epithélioma*; Ger. *Epithelkrebs*.

**DEFINITION.**—Cancerous disease of the skin and mucous membranes, caused by growth inwards of the epithelial cells of the rete mucosum and of the mucous membrane, leading to destruction of connective tissue and progressive ulceration.

**ÆTIOLOGY.**—Epithelioma is a disease of advanced age, occurring mostly after forty, although it is found occasionally in young, and, rarely, in very young, individuals. It is more common in men than in women, and is usually considered hereditary.

The frequency with which it begins in a wart, shows that certain histological conditions of the skin predispose to its development. The exciting cause is often to be found in local irritation, of which a striking example is seen in the frequency with which cancer of the lower lip in men is caused by the tobacco-pipe. Cancer caused by soot gives rise to chimney-sweep's cancer. It may develop in chronic ulcers, in lupus, in syphilitic scars, and in cicatrices. The irritation of bad teeth may cause it on the cheek. In Cashmere, where braziers are frequently applied to the abdomen and thigh, epithelioma occasionally results. Leukoplakia of the mouth in certain cases ends in cancer. Three cases have been reported in which it developed in warts growing on the hands of persons employed in tar and petroleum works. It may be set up by the irritation of old-standing eczema. In Kaposi's disease a great number of cancerous epitheliomatous ulcers develop in the skin, following the deposition of patches of pigment. Four cases have been reported in which epithelioma developed in old-standing psoriatic patches. It is, however, abundantly proved that chronic irritation of the most various kinds may, in certain persons, result in producing epithelioma; but in what the predisposition consists, or in what way the irritation produces the epitheliomatous growth, are questions upon which no light has yet been thrown.

**DESCRIPTION.**—In the early stage of epithelioma of the skin the affected surface is found

to be hard, more or less nodular, and characterised by small, closely-set, irregularly defined papules which are covered with epithelial scales. These scales are constantly being shed and re-formed; and if the detached epidermis is removed, a red granular surface is exposed. The thickened and elevated area gradually enlarges, forming a superficial hard tumour, which is raised above the level of the surrounding skin, with an abrupt margin. For some time the tumour moves with the skin in which it has grown; but, as it extends, it becomes fixed to the underlying tissues, and a growth is formed, which may either be of very limited extent, or may involve an area of considerable size. Eventually the growth ulcerates; or ulceration may occur so early that the initial indurated stage may not have been noticed, and the first morbid appearance that attracts attention is a small, dry, yellow or blackish crust covering a fissure in the epidermis.

Not infrequently the first development of epithelioma is in a warty growth which becomes fissured after having remained of a simple nature for a long period of time. The wart finally indurates, then ulcerates, and a typical epithelioma is the result.

The *epitheliomatous ulcer* has usually an uneven surface, and is irregularly bounded by hard, livid, everted edges. It is covered by minute granulations or by a greyish crust, which after removal is quickly renewed. It discharges a thin, scanty, sanious ichor, which is usually inoffensive; and it bleeds easily when touched. In some cases there is very little or no pain. In other cases the pain is severe and lancinating, or there may be stinging or pricking sensations, which cause frequent scratching and consequent irritation. The ulcer is usually round, oval, or elongated. Its essential character is the hardness of its borders and base, which is produced by the infiltration which is an invariable feature of the disease. The indurated boundary can be felt as a distinct mass adherent to the subjacent tissues. The borders are generally raised, sinuous, or nodulated, frequently everted, and sometimes undermined. The surface of the ulcer is concave, unequal, nodular, or warty. As the disease progresses, the ulceration extends in depth, and causes destruction of the subcutaneous tissues, muscles, and bones. Whilst ulceration and destruction are proceeding in the centre, the small papillary nodules with a scaly surface, which mark the early stage, are found on the circumference of the sore, and they may increase till they form small tumours before being finally involved in the extension of the ulceration.

In course of time the lymphatic glands corresponding to the affected part become enlarged, being felt at first as small, hard, movable, isolated tumours producing little inflammatory reaction. As they increase in size they

become incorporated in a single, somewhat lobulated mass, which eventually softens. From the infected glands the disease may extend further towards the trunk, but more frequently the proximate glands alone become cancerous. The affected glands may inflame, suppurate, and lead to cancerous ulcers, in which the peculiarities of the disease are reproduced. Secondary epitheliomatous growths are occasionally, but not frequently, found in the internal organs.

In the earlier stages of an epitheliomatous growth the destruction may take place chiefly in the corium, in which case the growth is not much elevated above the normal level of the skin. If, however, development takes place chiefly in the papillary layer, we have a permanent and warty growth, whilst if it grows freely in the subcutaneous tissue we have a deep-seated, flat, or rounded mass. These different varieties may more or less intermingle, and thus in the earlier stages of an epithelioma we may have a variety of appearances. This depends to some extent on the anatomical peculiarities of the part in which the disease develops. In all cases before ulceration takes place the affected part is unusually hard and enlarged. The lip, for example, pouts and projects like one overgrown.

The chief varieties of epithelioma are the *superficial* and the *deep-seated* forms, which respectively depend on the greater or less resistance opposed by the *pars reticularis corii* to the extension inwards of the epithelial growth. If the morbid epithelium be for a long time unable to penetrate the strong, firm bundles of the corium, and contents itself with 'cropping off,' as Erasmus Wilson has expressed it, the highly organised *corpus papillare*, we have a typical superficial form which, whilst it extends on the surface, makes an effort at healing in the centre. The disease presents the appearance of an extending cicatrix somewhat like that of a burn, the centre appearing to be healed whilst the advanced border which surrounds the cicatrix is in a state of slow ulceration. But when, either from the greater destructive power of the cancerous epithelium or from weakness of the fibrous tissues of the corium, the growing epithelium pierces the *pars reticularis*, the clinical aspects are much more serious, and are very different. The growth having once penetrated into the subcutaneous tissue, extends, usually with comparative rapidity, producing the destruction which is characteristic of deep-seated epithelioma. When the chief feature of the epithelioma is a projecting papillary growth, we have the so-called *papillary epithelioma* or *malignant papilloma*. This form is not infrequent when the disease develops in a wart. It may have begun as a papilloma or a papillary growth, or may develop subsequently on a superficial or more frequently on a nodulating,

ulcerating epithelioma. It may project considerably above the level of the surrounding skin, and may be seated either on a broad base or have a constricted neck, assuming a fungating form. The surface is formed of cicatrices and enlarged papillæ, which are cylindrical, pyriform, or conical, and single or in clusters. They are very vascular, the surface chiefly covered with an opaque, white cuticle, of a pink, vermilion, or brightly florid hue. When the loose epidermic scales are washed off, we have the granulated and lobulated surface known as 'cauliflower-like excrescence.' The epithelial cells may contain melanotic matter, which is also found between the cells, and we have then *melanotic epithelioma*. In *discoid epithelioma* there is a sharply bordered circular or oval disc, the margins being bounded by healthy integument, which is raised and slightly everted by the growth.

An epithelial cancer may grow up in the form of a cone, although such cases are rare. Sir James Paget removed one from the lower lip half an inch high, and nearly as much in diameter at its base, and another in a chimney-sweep's neck of a similar kind. In both cases the growth was covered with a thick laminated scab, not easy at first to distinguish from syphilitic rupia. Mr. Henry Morris has seen one in the outer dorsum of the foot in a man aged fifty-six. Or the growths may even be pendulous. Sir James Paget refers to growths on the lower lip and anus consisting of masses of very firm granulations far overhanging the adjacent healthy skin.

The tendency in all these forms is to produce continued destruction of healthy tissue, unless the morbid growth is removed by operation. In the later stages of the malady exhaustion supervenes, and the patient eventually succumbs, worn out by pain and increasing discharge from the ulcerating surface.

**SEATS.**—Epithelioma may develop at any part of the integument, but is most frequent on the *face*. In 102 cases 78 were on the face, 48 of these being in the lip, 4 were on the extremities, and 10 on the mucous membrane of the mouth. The local ravages may be very extensive before they cause death, and in the face may produce hideous deformity, laying bare the bones, teeth, and fauces, destroying portions of the skull until the *dura mater* is exposed.

The *lower lip* is a very common seat of epithelioma, which commences there either as a warty growth, or as a fissure from the edges of which the disease spreads. The whole lip becomes thickened and hard, projecting outwards, and allowing the saliva to flow from the mouth. The surface ulcerates progressively; and if the affected tissue is not removed, the disease extends to the mucous membrane of the cheeks, giving rise to

ulceration, and eventually the throat and bones become affected.

In the *penis* epithelioma may commence as a nodular swelling of the prepuce, or as a hard scirrhous infiltration of the glans, or between the prepuce and glans. In the latter case a discharge may be the first symptom observed. A tight prepuce and phimotic condition of the parts favour the development of the disease. In epithelioma of the glans and sulcus there early occurs thickening of the dorsal lymphatic vessel of the penis, which can be felt as a thick, hard, nodulated tract extending towards the pubes, to be continued towards the inguinal glands, which enlarge into hard, nodulated masses. Abscess and ulceration eventually occur.

Primitive epithelioma of the *vulva* frequently develops as a small warty tumour; at other times it is preceded by pruritus or a long-standing leukoplakia. The point of origin is not infrequently on the mucous surface of the labium majus, or at the junction of the skin and mucous membrane. There is usually a discharge of bloody, ill-smelling serum. A tumour may form as large as a nut or hen's egg, with a hard, shining, papillated surface. It may or may not be pedunculated. The labium minus may be the seat of infiltration of a hard consistence and reddish colour, and there may be a tumour, more or less pedunculated, of the clitoris. After the first symptom of pruritus there is a sensation of cold and fulness of the pelvis, especially in walking or standing. The progress is usually slow. At the beginning, epithelioma of the vulva may be mistaken for chronic granular vaginitis, or non-malignant tumour, and in the ulcerative period for a primary syphilitic sore or a gumma. The severe lancinating pains and extension of the ulceration remove the doubts which may have existed during an earlier period.

Epithelioma of the *anus* is rare. It occurs as a notched and protuberant growth at the anal orifice, and extends into the gut.

In the *limbs*, usually the leg, epithelioma mostly develops in cicatrices, varicose ulcers, syphilis, and lupus.

Epithelioma of the *mucous membrane* of the nose, conjunctiva, vagina, and rectum may appear either primarily, or secondarily as an extension from the adjacent skin. Cancer of the tongue and mucous membrane of the cheek is not uncommon, in which situations it may develop on the seat of syphilitic change, or on a patch of leukoplakia. On the tongue it begins as a raw granulated surface, which is sometimes thickly set with white points, tender to pressure; and it may be the seat of pain, nodular infiltration developing under the sore. Sometimes the nodular infiltration precedes the ulceration. On the mucous membrane of the cheek epithelioma is rarer, and is generally flat but sometimes fungoid when it occurs.

#### ANATOMICAL CHARACTERS AND PATHOLOGY.

The pathology of epithelioma may be summed up briefly in describing it as an epithelial neoplasm, which leads to the destruction of the vascular tissues amongst which it grows. From the rete mucosum there occur offshoots of epithelial growth, which travel along the papillary layer, pierce the corium, and (wherever they grow) produce, in the first instance, well-marked developments of inflammatory action. Wherever the epithelioma comes in contact with the vascular tissue, it acts like a poison, and evidences of destruction are found. The essential feature is not that there is a new growth of epithelium, but that there is a growth of a new kind of epithelium, which is, in effect, a connective-tissue poison. Like all poisons, this epithelial poison exerts an irritating influence on the adjacent blood-vessels, as is witnessed by abundant small cell infiltration, serous effusion, redness, and other evidences of engorged blood-vessels. Cancerous epithelium has then two abnormal qualities: one in that it grows inwards into the connective tissue; the second, that wherever it grows it produces inflammatory action. When a vertical section is made through the edge of an epitheliomatous ulcer, we find on the outer border which is adjacent to the healthy tissue prolongations inwards of the rete mucosum, whilst in the connective tissue of the papillary layer and cutis we find sections of apparently isolated masses of epithelial growth. These isolated masses, which are mostly in a cylindrical form, were really in unbroken continuity with growths from the rete; but as the growths, after they have penetrated downwards, follow to a certain extent the lines of least resistance, they cease to be in a direct line with the interpapillary cone from which they have come, and therefore, in a thin section, appear to be detached. It is this apparent isolation that led to the erroneous interpretation that epithelial cancer was caused by a heterologous growth of connective-tissue corpuscles. That in cancerous tissue the epithelium takes its origin in the rete mucosum is a fact that was recognised so long ago as 1852 by Hannover, but was lost sight of for many years after Virchow's views on cellular pathology became generally accepted. It was again clearly shown by Thiersch in 1865.

There is a special epithelial physiognomy peculiar to the morbid growth in each individual case. In many instances the cell columns undergo an extreme degree of horny change, and we find in the sections groups of very large horny cells clustering concentrically, giving rise to the so-called laminated capsules or 'nests.' In some cases the cell-columns do not take on the extreme horny metamorphosis, all the cells retaining the ordinary apparent characters of rete cells.

The large horny cells frequently break down, and in their cavities numbers of nuclei are found, an appearance which has suggested the theory of so-called 'mother' and 'daughter' cells. The appearance is, however, equally in harmony with the probable theory that leucocytes have found their way into the interior of the broken-down cells.

The new cells are generally supposed to be formed by cell-fission—a process, however, which is not found when sections are examined. Whatever the exact method may be by which this epithelial growth takes place, there is no reason to believe that in principle it differs from that which is characteristic of increase of epithelium in healthy conditions.

When the changes in the connective tissue which lead eventually to ulceration are carefully scrutinised, it is found that under the influence of the epithelial poison there is an extensive emigration of white and red corpuscles, a splitting up of the bundles of connective tissue into the primary or elementary bundles of which they are composed, and eventually disintegration of the bundles altogether, a granular detritus taking their place. Immediately under and bounding the ulceration, masses of small cells are found, numbers of engorged and dilated blood-vessels, and many free blood-corpuscles.

The diseased epithelium not only possesses the power of destroying the connective tissue, but finds its way into the lymphatic vessels, and by them into the lymphatic glands. Occasionally it is conveyed into the viscera, leading to cancerous deposits in the internal organs.

Attempts to associate cancerous developments with the presence of micro-organisms have not yet been confirmed. Dr. Yakimoff has stated that in cancer the blood-vessels, not only near the tumour but throughout the body, acquire thickened walls with diminished lumen. Mr. Ballance and Mr. Shattock have described in cancerous tissue, after sterile incubation, a projection of nuclear granules into the cell protoplasm, and they suggest that the stimulus which excites the epithelial growth may be due to these particles.

**DIAGNOSIS.**—Before ulceration has taken place it is possible in the early stage to confound epithelioma with sebaceous *acne*, with *warts*, and with certain forms of *lupus*. If in *acne sebacea* the crusts on the affected part are removed, by rubbing with soft soap or other means, a healthy skin with distended sebaceous follicles is laid bare, the disease not extending deeply into the true skin. In distinguishing between epithelioma and *lupus*, it is to be borne in mind that in *lupus* the patient is, as a rule, either young or has a history of having suffered from the disease in early youth. In *lupus* the characteristic infiltration will be found on or near the borders of the affected part. In an ulcerat-

ing *lupus* the edges of the ulcer are soft and regular and not everted. The ulceration extends more on the surface than in depth. It must not be forgotten that epithelioma may develop in the seat of *lupus*.

A *tubercular syphilide* is distinguished by the colour and grouping of the tubercles, which are multiple; whilst epithelioma begins usually by a single tubercle, runs a slower course and lasts longer, and is not affected by a course of iodide of potassium. The diagnosis between epithelioma and syphilis is sometimes difficult, and without microscopical examination is occasionally impossible. Syphilomata presenting this difficulty are not infrequent on the tongue and lower lip, the diagnosis being rendered difficult by their late appearance, and often by their long period of latency. In such cases it is of great importance that a small portion of the affected surface should be excised and subjected to microscopical examination. In syphilitic ulcers the ulceration progresses usually more rapidly than in epithelioma. The ulcers are multiple, whilst in epithelioma the ulcer is usually single. Whilst the tissues surrounding the epitheliomatous ulcer are infiltrated and hard, in syphilis the diseased surface is usually bounded by apparently healthy skin. The pain which is frequently present in epithelioma is not usually present in syphilis, and when it is present it yields to palliatives.

It may be difficult to distinguish between a *simple wart* and an epithelioma which begins in a warty growth. If a tumour of this kind develops in an elderly person, shows a tendency to spread, and is the seat of frequent desquamation with excessive formation of epidermis, the probability is in favour of epithelioma.

It is sometimes not easy to distinguish epithelioma on clinical grounds alone from *rodent ulcer*, which is a form of superficial cancer depending on a specific epithelial cell. A typical epidermic epithelioma and a typical rodent ulcer can be distinguished; but there are cases in which, without microscopical examination, the diagnosis for a time is impossible. Rodent ulcer produces less inflammation in the surrounding tissues, and usually after ulceration occurs; it takes place at first slowly and superficially. If the glands become affected we may feel confident that we are dealing with an epithelioma. Either of these forms may occur on any part of the body, but in the majority of cases epithelioma occurs on the lip, whilst rodent ulcer is found on the upper part of the face. The rolled-over edge, which is frequent but not constant in rodent ulcer, is very characteristic. See **RODENT ULCER**.

**PROGNOSIS.**—The prognosis in epithelioma of the skin is not so grave as that in other forms of cancer, because its course is slow, and because it is frequently well within reach of radical treatment. If removed sufficiently

early and completely it will not return at all. Metastasis is rare. The gravity in any special case depends upon whether the ulceration remains localised on the surface or penetrates deeply. In the deep-seated form the danger to life is considerable. The disease may last a long time before the health becomes seriously affected. Unless, however, relieved by successful treatment, the patient's strength eventually fails, the characteristic pain of cancer increases, and death usually takes place from exhaustion; sometimes from hæmorrhage caused by blood-vessels being exposed in the progress of the disease.

**TREATMENT.**—No medicines administered internally have any effect on this disease; but so long as the new-growth remains single and is within the reach of surgical treatment, we may hope for a successful result. As soon as the nature of the growth is ascertained, the whole of the diseased tissue should be removed, where this is possible, either by the knife or with caustics. The surgeon will naturally, when it is possible, have recourse to a cutting operation; and where the ulcer has attained a certain size and there is considerable infiltration present, complete excision of the whole of the diseased tissue is a very effectual method of dealing with the disease. In the early stages of the affection there is no doubt that it is within the reach of caustics. An epithelioma in a limited warty condition may, when the affected surface is small, be successfully treated in this way after scraping with a curette. In severe cases, too advanced to be reached by the knife, the progress of the disease may sometimes, to a certain extent, be arrested by cauterisation, under which the condition of the ulcerated surface improves, pain is diminished, the discomforts of the patient's condition lessened, and life prolonged. If the knife is used, it is necessary to cut well beyond the affected tissue, as there is little doubt that relapses, when they do occur, are due to the fact that a nidus of infected cells has been left behind, although they had not developed sufficiently to enable the surgeon to recognise the extent to which the disease had spread. We have found by microscopical examination of excised epitheliomata, that sections from the part next the line of incision have contained cancerous epithelium between the connective-tissue bundles.

The caustics generally used are caustic potash, chloride of zinc, pyrogallic acid, and arsenic. Caustic potash may be used either in stick or in solution. It has the advantage of being thorough in its action, and of not leaving much pain after it has been used. The growth, of course, should be thoroughly cauterised. Pyrogallic acid is used as a 10 per cent. ointment, which is spread on linen and kept continuously applied for from three to six days. It is less painful than chloride of zinc. Chloride of zinc is used as a paste in

the proportion of one part to three parts of gum mixed with a little water. The paste is laid over the diseased surface, which must be blistered if the skin is entire, the surrounding healthy skin being protected by adhesive plaster. A strip of plaster cover should be placed over the whole. The paste will destroy structures equal to three or four times its own thickness. The zinc paste which is used at the Middlesex Hospital is composed of equal parts of chloride of zinc and liquor opii, with sufficient flour to make it into a paste. Resorcin has been recently recommended for epitheliomata. There are cases in which it answers well; in other cases its action does not seem sufficiently energetic. The writer has used it as incorporated in Beiersdorf's (Hamburg) gutta-percha plasters, aiding its action by painting the surface with a solution in alcohol. The treatment is comparatively painless, and interferes little with the comfort of the patient. Lactic acid has also been recommended for epithelioma. It is supposed to have a destructive effect on the diseased tissue, whilst it spares the healthy structures; but the alleged advantages have not yet been sufficiently confirmed.

Amongst the various caustic pastes which have been used in epithelioma arsenical paste, as regards efficiency, occupies a high place, although, on account of the danger attending absorption, it requires special care. The writer cannot speak from his own experience; but he has the testimony to the merits of the paste recommended by Dr. Marsden of his friend Dr. MacLaurin of Sydney, who has used it extensively in hospital and private practice, and is satisfied that for a considerable number of cases it possesses very great advantages.

G. THIN.

**EPITHELIUM, Diseases of.**—The different kinds of epithelium must be separately considered, as they differ in their pathological relations—namely, *squamous* and *cylindrical* epithelium of mucous surfaces; *serous* epithelium, or *endothelium*; and finally *spheroidal* or *glandular* epithelium. The last kind will be better treated of under the heads of the several glands.

**A. DISEASES OF SQUAMOUS AND CYLINDRICAL EPITHELIUM.**—1. **Catarrhal Inflammation.**—Both varieties of epithelium occurring on mucous surfaces are subject to inflammation, which usually takes what is called the catarrhal form.

Catarrhal inflammation is characterised by hyperæmia, swelling of the tissue, rapid production and casting-off of cells, and increased production of the normal mucous secretion of the parts, without the production of any coagulable exudation, or any layer of new material. The cells thrown off are partly epithelial, partly leucocytes or pus-cells. The

secretion contains mucin. The proportion of the various factors of catarrhal inflammation varies greatly, sometimes hyperæmia with swelling, sometimes cell-production, sometimes fluid secretion predominating; and these differences sometimes mark different degrees or stages of the inflammatory process. When the number of leucocytes thrown off is very large, the catarrh becomes purulent, which differs only from the other in degree. Catarrhal inflammation is the ordinary result of irritation applied to a mucous surface; but it persists after the irritation has ceased, and has a marked tendency to become chronic. While the chief share in producing and maintaining the phenomena of catarrh must be referred to the condition of the blood-vessels which keeps up the congestion, and allows increased transudation and copious emigration of leucocytes, the part played by the epithelial cells in these processes is a point of great interest and importance, though as yet imperfectly determined. These cells, whether squamous or cylindrical, enlarge and alter in shape, sometimes containing vacuoles or mucous drops; while there must be (since so many are shed) a rapid new formation of them; but the seat of this new formation, whether in the normal or the pathological condition, is still obscure. All that can be clearly seen is that new epithelial cells grow up from the basement membrane by the side of the old ones. Further, it is not unusual to find swollen epithelial cells which show division of the nuclei or partial division of the cell itself, and others which show within their substance several smaller, roundish bodies, with the general character of young cells. These appearances have been regarded as indicating (1) multiplication of cells by fission, (2) endogenous cell-formation within the mother-cells, and (3) the origin of the numerous pus-corpuscles seen on the inflamed surface. There is, however, no reason for thinking that new epithelial cells, or still less that pus-corpuscles, are formed in this way. The presence of pus-corpuscles or young cells within the epithelial cells is probably an accidental complication, the young cells which possess the power of migration being absorbed into the protoplasm of the epithelial cells, so as to appear as if originally formed there. The production of vacuoles or mucous droplets in the epithelia appears to show an abnormally rapid production of mucus, and indicates also the death of the cell producing it. It is, therefore, an evidence of excessive mucous formation, and explains also the rapid desquamation of the mucous epithelium.

**2. Croupous Inflammation.** — Croupous inflammation is distinguished by showing, in addition to hyperæmia and swelling, the production of a layer of new material, or false membrane, easily detached from the surface. This form is usually, if not exclusively, seen on surfaces covered with cylindri-

cal epithelium, as in the air-passages. The false membrane, composed of fibrin cementing together layers of detached epithelium and leucocytes, does not owe its origin to any alteration of the epithelium itself.

Croupous inflammation of epithelial surfaces has been regarded as always indicating some specific form of inflammation. It now appears, however, that it may be produced by simple irritation, such as that which produces the catarrhal form, provided the irritation be sufficiently intense and destroys the superficial epithelium.

**3. Diphtheritic Inflammation.** — This is a name used with much variation of meaning, but generally to signify a process in which there is production of a false membrane closely adherent to the epithelial surface, and which is accompanied by some degree of necrosis or gangrene. In the production of the diphtheritic false membrane an important part has been assigned to the epithelium, it being held that the new material, which appears like exuded fibrin, is really produced by a metamorphosis (the so-called *fibrinous transformation*) of the pavement epithelium. It is pretty clear that when this condition occurs on surfaces covered with this variety of epithelium some such change in the epithelium does take place, but not that the membrane is made up wholly or even in any large degree of such altered cells. Moreover, even this cannot be clearly traced on surfaces covered with cylindrical epithelium. The membranes consist in large measure of cast-off epithelium, and also (as the writer holds) partly of fibrin, though the presence of the latter constituent is denied by some authors. It should be noted that the terms croupous and diphtheritic inflammation, as here used, are not synonymous with the diseases named croup and diphtheria. Micro-organisms, either micrococci or bacilli, especially the former, are always found in the diphtheritic false membrane. Some may be regarded as mere saprophytes, living in the dead tissues; but there is apparently at least one species, possibly more than one, capable of originating the morbid process, and causing necrosis of the epithelium. See DIPHTHERIA.

**4. Fatty Degeneration.** — It is very common to find the protoplasm of both squamous and cylindrical epithelial cells dotted with oil-globules, so much so that this must be considered normal, to a certain extent, in some glandular epithelium (as kidney), and does not appear to interfere with the function of the cells. When the fatty change, however, is extensive, and more especially when the whole body of the cell is opaque, the condition must be regarded as one of fatty degeneration (see FATTY DEGENERATION). This is seen in the stomach in cases of alcoholism, in poisoning with metals or phosphorus, and in cases which are probably nothing more than chronic catarrh. It is also seen in the alve-

ular epithelium in pulmonary emphysema. Fatty degeneration in epithelium appears to be a process leading to atrophy or destruction.

**5. Mucous or Colloid Degeneration.** Epithelial cells, especially in parts which are naturally adapted to the production of mucus, particularly cylindrical epithelium, are liable to undergo a form of degeneration in which a portion of their protoplasm becomes converted into mucous substance, and thus liquefied. Cells having this character are often seen in catarrhal conditions of the mucous membrane of the air-passages, but the change is probably only an exaggeration of the physiological production of mucus in the interior of the cell. It has not been traced in squamous epithelium.

**6. Albuminoid (Waxy or Amyloid) Degeneration.**—This form comparatively rarely affects epithelial cells, but still in cases of albuminoid disease we may sometimes find that the mucous surface of the intestines is stained with iodine in the characteristic manner. In one or two cases the writer has observed a similar change in the surface of the pelvis of the kidney, and even the bladder, where there has been albuminoid disease of the kidney.

**B. DISEASES OF ENDOTHELIUM.**—The single layer of flat epithelium found on serous surfaces, now generally known as *endothelium*, differs also in its pathological relations.

**1. Catarrhal Inflammation.**—This is unknown on serous membranes, their characteristic form of inflammation being exudative and fibrinous, corresponding thus to the

**2. Croupous Inflammation of mucous surfaces.** In this inflammation the endothelium does not necessarily take any part; though when the inflammation is once established, the endothelium, in part, is simply shed, in part shows changes of a proliferative kind; cell-division, multiplication, and endogenous cell-formation being observed here with less ambiguity (as it appears to the writer) than in the epithelium of mucous surfaces. Similar changes appear to occur in chronic inflammation of serous surfaces, and to play an important part in the production of fibrous adhesions between opposing surfaces.

**3. Fatty Degeneration.**—Endothelial cells are also subject to fatty degeneration, which may be very clearly seen in surfaces macerated by a collection of fluid, as in serous effusions of the peritoneum or pleura.

The other pathological changes of endothelium have not been studied.

The epithelium (or endothelium) lining the inner surfaces of the walls of arteries and veins closely resembles the endothelium of serous surfaces. It is very subject to fatty degeneration, as may be seen on examining atheromatous arteries. A distinct fatty degeneration of this tissue also occurs quite independently of atheroma, or of any in-

flammatory process. Proliferative changes have also been traced by some observers in the process of occlusion of ligatured arteries or veins obstructed by thrombosis; but they do not appear to play any important part in idiopathic disease.

**C. DISEASES OF GLANDULAR EPITHELIUM.**—The diseases of glandular epithelium are best spoken of under the head of diseases of the several glands. See BREAST, Diseases of; SALIVARY GLANDS, Diseases of; &c.

J. F. PAYNE.

**EPITHEM** (ἐπί, upon; and τίθημι, I place). A general term for a class of external applications which are soft and moist, such as poultices and fomentations. See FOMENTATIONS; and POULTICE.

**EPIZOA.**—See ENTOZOA.

**EPULIS** (ἐπί, upon; and ὄδον, the gum). See MOUTH, Diseases of.

**EQUINIA** (*equus*, a horse).—A synonym for glanders. See GLANDERS.

**ERETHISM** (ἐρεθίζω, I irritate).—A condition of excitement or irritation, affecting either the whole system or a particular organ or tissue. The word has been especially applied to the condition of the body in the early stage of acute diseases, and also to that induced by the too free use of mercury (*mercurial erethism*). See MERCURY, Poisoning by.

**ERGOTISM.**—SYNON.: *Morbus cerealis*; Fr. *Ergotisme*; Ger. *Ergotismus*; *Kriebelkrankheit*.

**DEFINITION.**—A disease due to the action of ergot.

**ÆTIOLOGY.**—This disease derives its name from the fact that it is the result of the ingestion of ergot—the sclerotium of a fungus called *Claviceps purpurea*, which grows parasitically in the ear of the rye. In some seasons this form of blight affects the grain so extensively that ten per cent. of the meal may consist of ergot. The phenomena to be described as symptoms of ergotism have been regularly and exclusively traced to the use of articles of food made from rye-meal thus contaminated. The appearance and severity of the disease vary with the amount of ergot consumed. Children at the breast are never attacked. Ergotism has frequently broken out in well-marked epidemics, after unfavourable harvests. In ruder times it constituted a severe form of scourge; but now it usually occurs sporadically, or is limited to families or small communities.

**ANATOMICAL CHARACTERS.**—Ergotism is characterised by definite anatomical changes, mainly in connexion with the vessels and the spinal cord. The arterioles are found *post mortem* to be contracted, and to be the seat of a peculiar hyaline degeneration of the

intima, with thrombosis and diminution, or even complete disappearance or occlusion, of their lumen. Gangrene is the ultimate result of these morbid changes. The posterior columns of the spinal cord are the seat of a degenerative or sclerosing process, somewhat resembling the lesion so familiar to us in locomotor ataxy.

**SYMPTOMS.**—Within a few days of the first ingestion of rye-meal contaminated with ergot, the ordinary phenomena of irritant poisoning are developed, namely, vomiting, diarrhoea, severe abdominal pains and cramps, and general depression—giddiness and headache being specially marked.

Along with the preceding, certain specific symptoms gradually make their appearance. The first and most characteristic of these is formication (a sensation of insects running along the skin), attended with severe itching of the extremities. The other special senses, such as vision and hearing, may also become disordered. Occasional tearing pains occur in the limbs, and clonic spasms of the muscles. Ravenous hunger is said to be a striking symptom in some instances. The pulse is infrequent and small. Respiration is not markedly disturbed.

The remaining phenomena peculiar to ergotism are usually described as belonging to two forms, the *gangrenous* and the *spasmodic*, according as the circulation or the nervous system is chiefly affected.

(a) *Gangrenous ergotism.*—The gangrene produced by ergot is peculiar only in respect of its cause. The toes, fingers, feet, ears, and nose are the parts most commonly attacked. The incipient discoloration, pain, and swelling are observed within a period of two days to three weeks from the commencement of the other toxic symptoms. The necrotic process passes through the ordinary stages of development; may be either 'wet' or 'dry,' and advances to complete separation of the part, if this have not been previously removed by operation.

(b) *Spasmodic ergotism.*—The leading symptom of this form of the disease is the occurrence of severe intermittent cramps or painful spasms, specially affecting the lower extremities. These develop into tonic contraction of the muscles, with fixation of the limbs; and end perhaps in general convulsions, prostration, various kinds of mental derangement, unconsciousness, and death. Abortion does not appear to be of frequent occurrence.

**COURSE, DURATION, AND TERMINATIONS.**—Many cases of ergotism are acute rather than chronic; but when gangrene appears, the course may be very protracted and variable. Spasmodic ergotism may last from two weeks to as many months. The mortality is said to have fallen from sixty to ten per cent. In a few cases, resolution occurs in affected extremities.

**PATHOLOGY.**—Beyond its effect as an irritant poison, the specific influence of ergot is mainly exerted upon the organs of circulation, the central nervous system, and the uterus. The different effects have now been satisfactorily traced to the actions of the different organic constituents of the diseased grain.

Cornutine, an alkaloid, one of the four important organic constituents of ergot, produces slowing of the cardiac rhythm by stimulation of the vagus at its central extremity. The contraction and hyaline change of the walls of the arteries are due to the action of a second constituent, sphacelinic acid. The result of these effects on the heart and arteries is that the blood-pressure rises. The gangrene is readily accounted for by the vascular changes, and is thus definitely referable to the sphacelinic acid.

The painful spasms, as well as the formication and other sensory disturbances, are the direct result of the action of the cornutine upon the spinal cord.

The action of ergot upon the uterus is explained by some authorities as due to stimulation by cornutine of the uterine centre in the cord. Other authorities maintain that it is set up by the local anæmia produced by the vascular contraction; whilst others, again, consider that ergot acts directly upon the muscular fibres of the organ.

**DIAGNOSIS.**—The occurrence of gangrene in a number of young and previously healthy persons, in countries where rye-meal is an article of food, should remove all difficulty from the diagnosis of ergotism. The spasmodic form of the disease can usually be distinguished from epidemic cerebro-spinal fever by the absence of pyrexia.

**PROGNOSIS.**—The prognosis depends chiefly upon the early recognition and removal of the cause. The probability of the escape of affected extremities may be estimated by the degree to which the gangrenous process has advanced.

**TREATMENT.**—The treatment of ergotism must commence with the removal of the cause. An attempt must then be made to hasten the elimination of the poison by the cautious administration of emetics and purgatives; to allay the symptoms of gastro-enteritis; and to support the strength of the patient by internal and external stimulants, such as alcohol, warmth, and friction. The treatment of less acute ergotism, including spasmodic cases, is symptomatic. Gangrene must be averted by careful local stimulation—by means, for example, of warm fomentations; or treated surgically if it make its appearance. See GANGRENE.

J. MITCHELL BRUCE.

**EROSION** (*erodo*, I gnaw).—A superficial destruction of tissue, caused especially by friction, pressure, corrosion, or certain forms of ulceration.

**EROTOMANIA** (ἔρως, love; and *μαυία*, madness).—**SYNON.**: Love-melancholy; Satyriasis (in men); Nymphomania (in women); Fr. *Monomanie érotique*; Ger. *Liebeswuth*.—Insanity characterised by excessive sexual excitement; sometimes symptomatic of cerebral lesion, sometimes of disorder in the reproductive organs. See **INSANITY**.

**ERRATIC** (*erro*, I wander).—Wandering, shifting, or irregular. Applied to pains, eruptions on the skin, and other morbid phenomena, when they shift or move from place to place.

**ERUCTATION** (*eructo*, I belch).—**DEFINITION.**—The sudden escape or expulsion of gas from the stomach upwards, with or without an admixture of portions of liquid or solid food, or of gastric juice or other liquids.

**DESCRIPTION.**—The act of eructation may be voluntary or involuntary. In the former case a small portion of air is first swallowed, and by the over-distension thus produced the escape of a portion of the gaseous contents of the stomach is favoured. When involuntary, we must suppose that the cardiac orifice, which is closed in the normal state of digestion, is relaxed, and thus permits the rejection of portions of undigested matter. From the violence with which eructations often take place, we may also assume that the muscular coat of the stomach contracts spasmodically at the same moment that the relaxation of the cardiac opening occurs. The nature of the material rejected varies greatly. Sometimes it is tasteless, at other times acid, and in rarer instances alkaline.

**ÆTIOLOGY.**—Eructations occur in all gastric diseases attended with an undue formation of gas. They are constantly complained of in atonic dyspepsia, more especially in that form which occurs in elderly people, and are probably the result of an imperfect contraction of the stomach, preventing the due expulsion of the digested food into the intestine. They form a prominent and distressing symptom in dilatation of the stomach. In such cases the patient often complains of a sense of fermentation in his abdomen, and immense quantities of gas are expelled, generally mixed with an acid or acrid fluid.

**TREATMENT.**—The indications in the treatment of eructations are to prevent the decomposition of food, and the formation of gases and other products; to restore tone to the stomach, and remove any morbid condition of this organ; and to give remedies with the view of absorbing gases, or assisting the act of eructation.<sup>1</sup> See **STOMACH, Diseases of**.

SAMUEL FENWICK.

<sup>1</sup> Hepatic disorder frequently requires attention, with remedies directed to the liver. Lavage may be called for in the severe type of eructation which attends dilatation.—Ed.

**ERUPTION** (*eruptio*, a bursting forth).—This term is commonly applied to a pathological manifestation in the skin, more or less general; sometimes marked by colour, sometimes by prominence, but more frequently by both. When sudden and hyperæmic, a term derived from the efflorescence of a plant, namely, *exanthema*, is employed, as in the instance of the exanthematous eruptions—scarlatina, rubeola, roseola, and variola. The term is equally applicable to less acute forms of dermatosis, such as urticaria, eczema, impetigo, ethyma, acne, and furunculus; and is also used for still more chronic forms of disease, for example, psoriasis vulgaris; and for outgrowths of the skin due to aberration of nutrition, as in the instance of warts and molluscous tumours. ERASMUS WILSON.

**ERYSIPELAS** (ἐρυθρός, red; and πῆλλα, skin).—**SYNON.**:—Lat. *Erysipelas*; Fr. *Erysipèle*; Ger. *Erysipelas*. Popular names:—St. Anthony's Fire (English); the Rose (Scotch); *der Rothlauf*, and *die Rose* (Ger.)

**DEFINITION.**—Inflammation of the integument tending to spread indefinitely (*Royal College of Physicians' Nomenclature of Diseases*). The vagueness of this definition indicates the looseness with which the term is employed. The features common to all inflammations usually spoken of as erysipelatous are fever, sometimes apparently preceding the local phenomena; and an inflammation tending to spread indefinitely by means of the lymph-spaces and lymphatic vessels of the affected part.

**SUMMARY OF VARIETIES.**—Erysipelas is usually divided into: (a) *simple cutaneous*; (b) *phlegmonous or cellulocutaneous*; and (c) *cellular or diffuse cellulitis* (Nunneley). In the first of these the inflammation is seated in the cutis vera, the subcutaneous tissue being often œdematous, but not actually implicated in the morbid process. There is practically no tendency to supuration in simple cutaneous erysipelas. In phlegmonous or cellulocutaneous erysipelas the subcutaneous areolar tissue is primarily affected, but the skin covering the inflamed area is speedily implicated. If not relieved by treatment, the inflammation tends inevitably to diffuse supuration, often accompanied by extensive sloughing of the cutaneous and subcutaneous tissues. In cellular erysipelas or diffuse cellulitis, deep-seated planes of areolar tissue are affected, such as those of the pelvis. The course of the disease is the same as in cellulocutaneous erysipelas, tending to terminate in diffuse supuration and sloughing. In addition to these three chief varieties, erysipelatous inflammation of the lymphatic vessels and veins, and of serous and mucous membranes, is also described.

**ÆTIOLOGY AND PATHOLOGY.**—All these affections grouped together as erysipelatous belong to the class of infective inflammations;

that is to say, they are dependent upon a virus which increases in quantity in the affected area, thus causing the characteristic spreading of the inflammation. The virus is present in the fluids of the inflamed area, and the disease can be communicated from one individual to another by inoculation of the inflammatory products; and in the case of cutaneous erysipelas, at least, there seems reason to believe that the poison may also be carried by the air. In all erysipelatous inflammations the virus diffuses itself by the lymph-spaces and lymphatic vessels of the affected part, showing little or no tendency to invade the blood-vessels, and to be disseminated by the blood-stream to distant parts. It is probable that there is more than one virus which may thus give rise to a spreading lymphatic inflammation; but in the vast majority of cases clinically described as erysipelas, which have been submitted to examination, a micro-organism of a definite form has been found, which is believed to be the actual virus. In 1869 Hueter suggested that the virus of erysipelas was probably a micro-organism, and thought that he had found it in the discharges of the inflamed part. In 1880 Lukomsky, Tillmanns, and others discovered the presence of micrococci in the lymph-spaces of the skin at the advancing edge of the rash in cutaneous erysipelas; but in 1882 the relation of these organisms to the disease was clearly demonstrated by Fehleisen. A small piece of the skin from the advancing edge of the rash was removed with proper precautions to avoid contamination, and planted upon some nutrient gelatine. From this a film soon spread over the gelatine, which on microscopic examination proved to be a pure cultivation of a micrococcus. The organism belongs to the genus streptococcus—that is to say, it shows a tendency to grow in chains or pairs. It does not liquefy the gelatine in its growth. This organism, after cultivation for several generations upon gelatine, gave rise to typical erysipelas when inoculated on the ear of a rabbit. Subsequently inoculations were made on the human subject with the intention of setting up erysipelas for the relief of lupus or incurable cancer. Seven cases were thus treated and genuine cutaneous erysipelas followed the inoculation in six; the seventh patient had recovered from an attack of erysipelas a few months before. Other observations seemed to show that one attack of erysipelas confers upon the patient a short period of immunity to the disease.

In all forms of cellulo-cutaneous erysipelas and in diffuse cellulitis a streptococcus exactly resembling that described by Fehleisen is found in the fluid filling the lymph-spaces of the affected part, whether it be purulent or serous. It cannot be distinguished from that found in cutaneous erysipelas by its reaction to aniline dyes, by its mode of growth, or

microscopic appearances. To this micrococcus Rosenbach gave the name of streptococcus pyogenes. Cultivations of this organism cause acute suppuration when inoculated on animals; but it has lately been asserted that when inoculated superficially on the ear of a rabbit typical cutaneous erysipelas is set up. It has been stated that cultivations of the streptococcus erysipelatosus from the human subject injected into the subcutaneous tissue of the rabbit have given rise to deep-seated phlegmonous inflammation and suppuration. This is, however, denied by Fehleisen, who asserts that he has repeatedly injected erysipelas micrococci into the subcutaneous tissue and muscles of rabbits without causing inflammation or suppuration. The identity of the organisms must, therefore, be considered an open question at the present time. Clinically the simple cutaneous variety of erysipelas differs so widely from the subcutaneous forms that it is difficult to believe they are due to the same virus. In cutaneous erysipelas the streptococci are found in the lymph-spaces of the cutis at the advancing margin of the rash. Their presence excites the ordinary phenomena of inflammation—the blood-vessels are injected, and abundant migration of colourless corpuscles takes place. These seem to destroy the micro-organisms, which are not to be found in the more central parts of the rash. The persistence of the phenomena of inflammation in the parts in which no streptococci can be demonstrated must be supposed to be due to the damage done to the tissues by the chemical products formed during the growth of the organisms. The organisms never enter the blood-vessels locally, and though very probably some may find their way into the blood-stream by the lymphatics, there is no reason to believe that they multiply in the blood. The constitutional symptoms are therefore due to the entrance of the chemical products of the local process into the blood-stream, and not to any general infective process. In phlegmonous erysipelas and in cellulitis the streptococci can be easily demonstrated in the inflammatory exudation filling the lymph-spaces in the whole affected area, and not only at the advancing margin; but, as in the cutaneous form, the organisms have not been proved to infect the blood. Further evidence of the absence of blood infection is furnished by Fehleisen's experiment on the rabbit's ear. Having induced typical cutaneous erysipelas by the inoculation of a pure cultivation of the streptococcus, he amputated the ear with a Paquelin's cautery, with the effect of immediately relieving the elevation of temperature and all other constitutional symptoms. It is not proved, however, that the virus may not enter the circulation from the alimentary canal or the air-passages, and be carried by the blood, without actually infecting it, to some part

which, from local injury or other cause, may form a suitable point for its development. On the assumption that the streptococcus is the actual virus, this seems the only possible explanation of many cases of erysipelas, especially of the cellulose-cutaneous or cutaneous variety, in which no evidence of direct inoculation by a wound or otherwise can be obtained.

The streptococcus grows readily at ordinary temperatures on gelatine, agar-agar, and potatoes, and probably on almost any damp organic matter. It has been said to have been found on the floor of an affected ward. This explains the well-known fact that hospital wards are apt to become infected, case after case breaking out until the ward is closed and disinfected. In military practice, erysipelas is very rare except in cases treated in civil hospitals. In this respect it differs from hospital gangrene and pyæmia, which can always be generated by crowding the wounded in buildings of any kind. It seems probable therefore that the virus is really specific, like that of scarlet fever or smallpox. That it can be carried by the air seems also to be proved, as the streptococcus has been detected on potato cultivations made from the air of infected wards. The cultivations thus obtained gave rise to erysipelas when inoculated on a rabbit. There is little doubt, however, that it is more commonly conveyed by the hands or clothes of the attendants. Erysipelas certainly does not show the same degree of infectiousness as most of the acute specific diseases.

The micro-organism is killed in 45 seconds by a 1 in 30 solution of carbolic acid, and in 15 seconds by a 1 in 1,000 solution of perchloride of mercury.

All the evidence above given tends therefore to show that erysipelas is a local disease, dependent on the invasion of the tissues by a specific micro-organism, and that the constitutional disturbance is secondary to the local. The opposite view has been held by many authorities, who have classed erysipelas with the acute specific fevers, regarding the rash as the local manifestation of a general condition. The arguments in favour of the latter are briefly as follows: (a) In many cases there is a distinct period of invasion in which the constitutional symptoms are present without the local; (b) there is frequently no evident point of inoculation; (c) the constitutional symptoms in cutaneous erysipelas are often much more severe than the local inflammation seems sufficient to account for.

Against these it is urged by those who support the local theory: (a) that even during the apparent period of invasion without local phenomena, a careful examination will detect some swelling of the lymphatic glands or other evidence of local mischief; (b) that the minutest abrasion merely being necessary for inoculation, it is very easily overlooked; and (c) that when we consider the intensely

poisonous nature of the products of the growth of micro-organisms in albuminous fluids, the constitutional symptoms are not greater than might be expected. The results of the inoculations, and Fehleisen's experiment of amputation of the rabbit's ear above mentioned, and the fact that inoculation of the blood has never communicated the disease, nor have organisms been satisfactorily demonstrated in it, are further proofs of the local nature of the disease. Moreover the disease does not run a definite course like an acute specific fever. The fever continues as long as the rash is extending, and ceases as soon as that comes to an end. It must be remembered, however, that it is not proved that the blood may not serve as a carrier of the virus, though not as a medium for its growth, as in many other infective diseases—tubercle, for example. Granting therefore that erysipelas is an infective disease, and that the micro-organism above described is the actual virus, the predisposing causes may be divided into (1) *those favouring the growth and dissemination of the organism out of the body*; and (2) *those predisposing the patient to receive it*.

1. (a) *Accumulations of decaying animal or vegetable matter*, upon which the organism can develop, will predispose to the disease. Thus the presence of a dust-heap near a window of a ward, has been known to cause repeated outbreaks of erysipelas in the nearest bed. Dampness of the floors, from repeated washing, has also been said to predispose to erysipelas. Decomposing discharges from wounds, and want of cleanliness in dressings, are also important causes. (b) Certain meteorological conditions are said to predispose to erysipelas. East winds, low temperature, excessive moisture, cold and heat, have all been considered causes, but the evidence on these points is very unsatisfactory. It is certainly least common in the hottest and driest part of the year, and more common in spring and late autumn. (c) Bad ventilation leads to concentration of the virus and increases the chances of infection. (d) The virus can undoubtedly be carried by the medical and other attendants, but risk of this happening is greatly diminished by the proper use of antiseptics.

2. (a) A constitutional predisposition to erysipelas is occasionally met with, which is sometimes hereditary. The patient usually suffers from repeated attacks of the disease. One attack of erysipelas is therefore said to predispose the patient to another. (b) Exposure to the impure atmosphere of badly ventilated or overcrowded wards increases the liability to erysipelas. (c) Imperfect hygienic conditions generally, such as bad or insufficient food, impure water, &c., predispose the patient to the disease. (d) Diseases of the liver or kidneys make a patient especially liable to it. (e) The abuse of alcohol is one of the most important of all predisposing

causes. The great majority of the cases of fatal phlegmonous erysipelas occur in hard drinkers. (f) Age has no influence. (g) The disease is said to be more common in women, especially at the menstrual period. (h) The presence of a wound or abrasion to serve as the seat of inoculation is the only important local predisposing cause of erysipelas.

Erysipelas undoubtedly occurs in *epidemics*, and the type of the disease varies in different outbreaks. We know nothing of the causes which render the disease epidemic.

We shall now proceed to discuss in detail the several varieties of erysipelas summarised above.

**I. Simple Cutaneous Erysipelas.**—This is the most typical form of the disease.

**ANATOMICAL CHARACTERS.**—The *post-mortem* appearances of erysipelas are by no means characteristic. The redness of the inflamed area of course fades after death, leaving a faint yellowish tint. The skin feels hard and inelastic, and the subcutaneous tissue contains an excess of serous fluid. In very acute cases there may be the usual signs of blood-change seen in all malignant fevers: early *post-mortem* staining, imperfect coagulation of the blood, subserous petechiæ, swollen and soft spleen, and cloudy swelling of the liver and kidneys. Hiller states that microscopic examination of the blood before death shows many of the white corpuscles to have undergone degenerative changes and become converted into masses of highly refracting granules. Busk has described plugs of such altered corpuscles in the small vessels of the lung, and Bastian has observed a similar condition in the vessels of the brain. Microscopic examination of the affected part of the skin shows large numbers of migrating leucocytes, lying in the spaces of the fibrous tissue, amongst the fat-cells, and in the lumen of the lymphatic vessels. They are especially abundant round the small vessels. The micro-organisms found in the lymph-spaces of the skin at the advancing margin of the rash have been already described.

**SYMPTOMS.**—In simple erysipelas the constitutional symptoms often appear to precede the local. The invasion is marked by chilliness, seldom by an actual rigor; loss of appetite; general malaise; nausea, but seldom actual vomiting; headache; pain in the limbs; and the usual signs of pyrexia. The invasion is tolerably sudden. The temperature rapidly rises, to about 103° F., or higher. The rarer symptoms at this stage are epistaxis in adults, and convulsions in children. Usually within twenty-four hours of the invasion the characteristic cutaneous inflammation becomes evident. It may, however, commence simultaneously with the febrile disturbance, or be delayed even for two or three days. Frequently the lymphatic glands nearest to the part are swollen before the cutaneous eruption appears; afterwards

they are invariably enlarged and tender. The local inflammation usually, if not always, starts from some wound, scratch, or abrasion. It commences indifferently in a fresh wound or a granulating sore. When no wound can be recognised as its starting-point, it usually starts from the junction of mucous membrane and skin, most commonly from the corner of the eye, causing a swelling across the bridge of the nose. It may also start from the angle of the mouth, the external auditory meatus, or the anus. It may commence in the nasal fossæ or pharynx, and extend outward to the skin of the face. Possibly in all cases it starts from some slight abrasion which is scarcely to be detected (Trousseau). The inflamed skin is bright red in colour, with sometimes a yellowish tinge; the redness advances in all directions, but usually most rapidly in that of the lymph-stream. The advancing margin is irregular, sharply defined, and very slightly raised. The cutis is œdematous, and pressure with the finger-nail leaves a deep and abiding mark. Where the subcutaneous areolar tissue is lax, as in the eyelids or scrotum, it also becomes greatly swollen. In the limbs the subcutaneous swelling is great only in severe cases. In many cases small vesicles rise, which may coalesce, forming blebs of considerable size. These ordinarily contain clear yellow serum, which, in bad cases, may be stained with blood-pigment. As these bullæ burst they dry up, forming scabs on the surface, but no ulceration takes place beneath these scabs. The inflammation has but little tendency to end in suppuration; when this does occur it is in those parts in which the œdema has been greatest, as the eyelids. There is heat, tension, and pain in the affected part, and a peculiar sensation of stiffness, which may even precede the appearance of the redness.

The febrile symptoms which usher in the attack remain unrelieved so long as the redness continues to spread. The pulse is at first quick and full, but it soon loses force, and in bad cases becomes extremely rapid and feeble. It is by the pulse, more than anything else, that the gravity of the case is marked. The temperature seldom rises above 106° F., though 107.5° F. has been recorded. The daily variations are not great, there being merely the usual slight morning fall and evening rise. Delirium is not uncommon at night, even in mild cases. In erysipelas of the head it may be a prominent symptom. It is usually due to the blood-condition, and not, as was formerly supposed, to extension of the inflammation to the membranes of the brain. This, however, does occur in rare cases, especially in erysipelas of the orbit, or in that following a compound fracture of the skull. The tongue is always foul, and usually dry; in bad cases becoming cracked and brown, with sordes on

the lips and teeth. In erysipelas of the head the fauces are always red and congested, even when the inflammation has not actually extended to that part. The bowels are sometimes confined, but diarrhœa with offensive motions is liable to occur. There is nothing characteristic about the urine. As in other acute febrile diseases, it frequently contains a small quantity of albumen. In erysipelas of the head, when the disease reaches its height, the appearance is often hideous in the extreme, the features being completely obliterated by the swelling of the lax subcutaneous tissue, and the face further disfigured by the scabs formed by the dried blebs.

The duration of simple erysipelas is very uncertain. The cessation of the disease is marked by the inflammation ceasing to extend, and by a simultaneous fall of temperature, often very sudden. This may occur as early as the fifth day, or be delayed till the end of the second or middle of the third week. As the rash fades its margin loses its distinct outline, and the redness shades off insensibly. It is not uncommon to see the inflammation spreading at one part, fading at another. After the subsidence of the inflammation there is desquamation of the cuticle, and in erysipelas of the head often complete loss of hair, which is, however, never permanent. Even after a mild attack the patient's strength is much reduced, and he often remains weak and anæmic for a considerable time. Relapses are by no means uncommon. When death occurs from simple cutaneous erysipelas, it arises most frequently from exhaustion. It may also be due to the gravity of the blood-change. Occasionally the fatal termination is preceded by violent delirium ending in coma. Sometimes it is due to complications, as pleurisy or pneumonia, or in very rare cases meningitis. When sloughing of the skin or suppuration occurs, death may take place from septicæmia or pyæmia.

**VARIETIES.**—Some writers have divided simple erysipelas into *medical* and *surgical*—or *idiopathic* and *traumatic*, and have described these varieties as distinct diseases. They are, however, probably identical, for the following reasons: they closely resemble each other in mode of invasion, course, and pathological changes; infection from so-called idiopathic erysipelas will give rise to the traumatic form in patients suffering from an open wound; and during an outbreak of erysipelas in a surgical ward, patients without open wounds are occasionally attacked by the idiopathic form. Erysipelas has also been subdivided according to the part it attacks, as erysipelas faciei, capitis, scroti, &c.

Erysipelas occasionally affects the mucous membrane of the pharynx and upper part of the larynx. This form presents some peculiarities, and is spoken of as *erysipelatosus pharyngitis* and *laryngitis*. The invasion and constitutional symptoms are similar to

those of simple cutaneous erysipelas. There is a bright redness of the back of the pharynx and the fauces, always accompanied by considerable œdema of the soft palate and some swelling of the tonsil. The glands at the angle of the jaw are swollen and tender. The danger of this affection arises from extension to the glottis, causing œdema glottidis, with intense dyspnoea, expiration being more easy than inspiration, and both liable to obstruction by spasm. In such cases tracheotomy or laryngotomy may be required at any moment, to prevent death from asphyxia. In other cases the inflammation may extend forwards and appear on the face, either at the nostril or mouth, and afterwards extend as ordinary facial erysipelas.

Erysipelas occasionally attacks new-born infants, starting from the navel or genitals. This form has been spoken of as *E. neonatorum*. Serous membranes, especially the peritoneum, are said sometimes to be affected by erysipelas following wounds. In lying-in women the poison of erysipelas seems, in common with that of many other unhealthy inflammations, to be capable of causing puerperal fever.

Dermatologists have, according to their wont, invented a name for every possible variation. Thus when the inflammation spreads at one part while fading at another it has been called *E. ambulans* or *erraticum*; when spreading in a winding course, *E. serpens*; when causing small vesicles, *E. vesiculare* or *miliare*; when blebs form, *E. bullosum*; when there is much swelling, *E. œdematosum*, &c. Such names are useless, and might be multiplied *ad infinitum*.

**DIAGNOSIS.**—When erysipelas is fully developed it is scarcely possible to mistake the disease. During the stage of invasion, before the appearance of the rash, diagnosis is impossible. Simple diffuse inflammation around a wound or abscess is distinguished from erysipelas by the absence of the characteristic invasion, and of the sharply defined border. Simple erythema differs from erysipelas in the absence of fever, and in the eruption being composed of numerous isolated patches. Occasionally, in malignant smallpox, there may be much redness and swelling of the face before the appearance of the vesicles, but the symptoms of invasion are much more severe than those of erysipelas.

**PROGNOSIS.**—The prognosis depends chiefly upon the gravity of the general symptoms. The following are bad signs: high fever, violent delirium, excessive diarrhœa, early prostration, and very dry tongue with sordes. The extent of the inflammation is of less importance. Old age, disease of the kidneys or liver, and especially chronic alcoholism, add greatly to the gravity of the case. When erysipelas affects the pharynx there is always danger from œdema glottidis. In uncomplicated cases the death-rate is not high. Of

25 patients treated in the medical wards of University College Hospital for facial erysipelas from 1872 to 1876, only one died, and he was suffering from chronic Bright's disease.

**TREATMENT.**—1. *Constitutional.*—Erysipelas being a most exhausting and depressing disease, no antiphlogistic treatment is ever justifiable. Clear the bowels at the commencement of the attack, but avoid violent purgation. Only two drugs have any reputation in the treatment of erysipelas. The tincture of perchloride of iron, in large and repeated doses, has been strongly recommended by Dr. Reynolds and others, and is stated by some to act as a specific. To be of any use it must be given in doses of forty minims every four hours. Aconite, if administered as soon as the temperature begins to rise, is said to cut the attack short. It may be given in half-minim or minim doses of the tincture, at first every quarter of an hour for one or two hours, and afterwards hourly, till the skin becomes moist and the temperature falls, but its effects must be very carefully watched, to avoid dangerous depression. The *diet* must be as nourishing as possible—beef-tea, eggs and milk, &c. Solid food can never be taken during the advance of the disease. Stimulants are usually required, and the amount must be regulated by the pulse. Large quantities are often necessary.

2. *Local.*—Local treatment is very various. Warmth and avoidance of variations of temperature are essential. Cold is utterly inadmissible; it aggravates the inflammation, and tends to cause suppuration or even sloughing. Hot fomentations or hot baths may be employed when the part affected renders them admissible. In other cases dry warmth must be used; it is best obtained by covering the affected part with a thick layer of cotton-wool. Poultices should be avoided, as they needlessly irritate the skin, and are dirty and apt to get cold. With the application of warmth innumerable varieties of local applications have been recommended. These may be divided thus: (a) *Indifferent applications.* These are intended only to exclude the air, but they have the disadvantage of shutting in the secretion of the skin. The most common of these are collodion, oil, and a thick layer of flour or starch under cotton-wool. (b) *Sedative applications.* The most important remedy of this class is belladonna. It is best applied as a paint composed of equal parts of the extract and glycerine. It is especially useful when there is much inflammation of the lymphatic vessels and glands. (c) *Powerful astringents.* Valette, of Lyons, recommends a 30 per cent. solution of perchloride of iron; Higginbottom a solution of the 'brittle stick of nitrate of silver'—20 grains to one drachm of water. Before applying either of these, the skin must be carefully washed with soap and water to free

it from grease. The perchloride of iron must be rubbed in with a glove. (d) *Antiseptic applications.* Marshall recommends creasote made into a paste with kaoline; Dewar, equal parts of sulphurous acid (B.P.) and glycerine. Tincture of iodine is a common application. Koch recommends an ointment composed of creolin 1 part, iodoform 4 parts, and lanolin 10 parts. Hueter practised the subcutaneous injection of a 1 in 30 solution of carbolic acid. He stated that this causes an immediate arrest of the inflammation for a small distance round the puncture; if, therefore, the treatment be adopted at so early a stage that the area of inflammation can be surrounded by four or five punctures, the disease may be checked. Beyond this there would be danger of carbolic-acid poisoning. Kraske and Riedel recommend scarification of the advancing margin with a special instrument, and the subsequent application of lint soaked in a 1 in 500 solution of corrosive sublimate. (e) *Drawing a limiting line* in front of the advancing rash. This has been done with solid nitrate of silver and with blistering fluid. It is utterly useless. Wölfler recommends the application of pressure immediately in front of the advancing line of redness by means of adhesive plaster. He believes this prevents the invasion of the lymph-spaces by the micrococci.

Erysipelas of the fauces is best treated by the local application of a strong solution of perchloride of iron. If there be œdema glottidis the swollen parts must be scarified, and if this fails to give relief, tracheotomy may be necessary.

**II. Phlegmonous or Cellulo-cutaneous Erysipelas.**—This was described by Dupuytren under the name of 'diffuse phlegmon.'

**ANATOMICAL CHARACTERS.**—Incisions made into the inflamed part in the early stages show the spaces of the areolar tissue distended with a semi-solid inflammatory exudation; a little later this is found to be a turbid and puriform fluid; later still the subcutaneous cellular tissue is represented by masses of shreddy sloughs soaked in pus. Unless exposed to the air by incisions or by sloughing of the skin, these sloughs are free from any odour of decomposition, and contain no gas. The streptococcus already described can invariably be demonstrated in the exudation fluids of the affected part. There is nothing characteristic in the *post-mortem* appearances of the internal organs.

**SYMPTOMS.**—The invasion is usually marked by chilliness or a rigor, elevation of temperature, nausea, headache, and general malaise. The local inflammation may commence in some wound or abrasion, but it may also arise spontaneously. From the beginning there is marked œdema of the subcutaneous tissue. The skin is reddened, but the margin of the redness is not sharply

defined, and swelling and tenderness of the lymphatic glands are often absent. As the area of inflammation extends, the affected part becomes tense and brawny, and vesicles or large blebs form. The tension may become so great that firm pressure with the finger scarcely makes any impression. In a few days from the commencement of the disease, the greater part of a limb may be involved. If unrelieved by treatment, the tint of the redness becomes more dusky, and dark purple patches appear. At the same time the tension becomes less, and gives place to a soft, boggy feeling, indicating sloughing of the subcutaneous cellular tissue. Then livid patches appear, which break down into sloughs. As these sloughs separate, large shreddy masses of gangrenous cellular tissue can be drawn out, leaving the undermined skin connected with the deeper parts only by bands containing the larger vessels. Finally, the remaining skin being insufficiently nourished may become thin and melt away, leaving large tracts of the fascia or muscles beneath exposed to view. In this way, if proper treatment be not adopted in time, the greater part of a limb may be denuded of its cutaneous and subcutaneous covering. The extreme stage may be reached in a week or ten days, but a longer time usually elapses before all the sloughs have separated. In the earlier stages there is much burning and tensile pain, but this subsides as gangrene sets in. The constitutional symptoms are grave from the beginning. There is high fever, the thermometer often reaching 105° F. The tongue is dry and brown, and *sordes* accumulate on the lips and teeth; there is total loss of appetite; and diarrhoea is a frequent symptom. The pulse, at first full and bounding, soon loses force, becoming rapid and weak. Delirium, usually of the muttering type, is always present in severe cases. Death occurs from exhaustion, or from some complication, such as pneumonia, pleurisy, &c. During the separation of the sloughs septicæmia and pyæmia are of frequent occurrence. The disease most commonly attacks one of the limbs, but it is occasionally seen in the scrotum, and a peculiarly virulent form has been described as affecting the face. Phlegmonous erysipelas most commonly occurs in adult patients of broken constitution, suffering usually from the effects of the abuse of alcohol, or from some disease of the liver or kidneys.

**DIAGNOSIS.**—From simple erysipelas the phlegmonous form is distinguished by the great swelling and brawny hardness, by the want of a sharply defined edge, and by the early tendency to sloughing; from spreading gangrene by its slower progress, and the absence of the rapid decomposition and development of gas in the tissues. Acute necrosis somewhat resembles it, but this

disease is limited to young subjects, the swelling is less brawny, and when pus forms there is distinct fluctuation and not the boggy feeling of phlegmonous erysipelas.

**PROGNOSIS.**—The prognosis is always grave, especially if there be any delay in adopting the proper treatment. Early failure of the heart's force, excessively dry tongue, diarrhoea and vomiting are bad signs. The gravity of the case increases directly with the area affected.

**TREATMENT.**—The patient must be supported by good beef-tea, milk and eggs, and stimulants are usually required to be freely given. No depletory measures are ever justifiable. Ammonia with bark is sometimes of service. *Locally* the treatment in very mild and doubtful cases must consist in the application of hot fomentations, and extract of belladonna made into a paint with an equal amount of glycerine. As soon as there are any signs of tension, free incisions must be made to relieve it. The strictest antiseptic precautions should be adopted in making these incisions, and some efficient antiseptic dressing applied afterwards. Hot boric acid fomentations frequently changed, or sheets of salicylic wool (10 per cent.), moistened with boiling water and applied like a poultice, will be found very useful.

**III. Diffuse Cellulitis, or Cellular Erysipelas.**—In this disease the inflammation is confined to the subcutaneous cellular tissue, or to the planes of areolar tissue amongst muscles or beneath fascia. The course of the inflammation is similar in many respects to that of phlegmonous erysipelas, the only important difference being that the skin remains unaffected, or is only implicated in the later stages, as a consequence of the sloughing of the subcutaneous tissues.

**ANATOMICAL CHARACTERS.**—The *post-mortem* appearances are similar to those of phlegmonous erysipelas.

**SYMPTOMS.**—The local signs of diffuse cellulitis, when occurring in the subcutaneous tissue or beneath the superficial fascia, are marked œdematous swelling, gradually becoming brawny, slight redness of the skin, and usually mottling from over-distension of the superficial veins. There is no sharp limit to the swelling. There is intense tensile or burning pain, increased by movement, and acute tenderness on pressure. The neighbouring lymphatic glands are in most cases swollen and tender. As the disease advances, the swelling becomes doughy, and possibly an indistinct sensation of fluctuation may be felt. The skin now becomes redder, and the gangrenous inflammation may even extend to it, unless prevented by treatment. An incision in the œdematous or brawny stage merely shows the areolar spaces distended with serum, sometimes clear, more often turbid. If the incision be

delayed till the later stages, the affected cellular tissue is reduced to a mass of shreddy sloughs soaked in pus. Gas does not form amongst these sloughs till after air has been admitted from without. In mild cases the inflammation may localise itself, and lead to the formation of a large abscess. The constitutional symptoms are always grave. The temperature is high, 104° to 106° F. There are the usual symptoms of fever; the tongue is foul and speedily becomes dry; vomiting and diarrhoea are not uncommon; the pulse, at first quick and full, soon becomes feeble and rapid. There is almost always delirium. The disease usually runs a rapid course, two or three days sometimes being sufficient for it to reach its extreme stage.

Diffused cellulitis, as above described, is most frequently the result of a poisoned wound; it may then start from the wound or make its appearance at a distant part. It forms the most fatal variety of *post-mortem* wound; and, as is well known, in such cases the puncture may appear healthy, whilst the areolar tissue in the pectoral region may be the seat of most acute diffused inflammation. The bite of the less poisonous reptiles causes a similar diffuse inflammation. Diffuse cellulitis of the pelvis is a common cause of death after lithotomy, and is not uncommon in women after labour. Diffuse cellulitis beneath the pericranial aponeurosis is of frequent occurrence after scalp wounds. Occasionally the disease arises spontaneously, and it is then most common in the upper limb; but it has been seen in the areolar tissue of the neck and in many other regions. In pyæmia and septicæmia patches of diffuse cellulitis may appear in intermuscular spaces, or in the subcutaneous tissue.

**DIAGNOSIS.**—The diagnosis of cellulitis is often difficult when the mischief is deep-seated. The œdema, pain, and tenderness, with the severe constitutional symptoms, are the chief guides; but even when these are well-marked, the extent of the inflammation and the necessity for active treatment are often difficult to determine.

**PROGNOSIS.**—This depends much upon the cause, and upon the previous health of the patient. It is a very bad sign when the gravity of the general symptoms is out of proportion to the local mischief. In the pelvis cellulitis may be fatal from peritonitis; in the neck it is very fatal; it is much less dangerous in the limbs. When it occurs as a part of pyæmia or septicæmia the prognosis is of course very grave.

**TREATMENT.**—Early incisions into the inflamed cellular tissue, with antiseptic applications and abundant support, form the only reliable treatment in severe cases. In slight cases the application of extract of belladonna and glycerine (equal parts), with hot fomentations, may lead to resolution or limitation of the inflammation.

**IV. Erysipelatous Lymphangitis.**—Inflammation of the superficial lymphatic vessels is a common accompaniment of all varieties of erysipelas; but in some cases it forms by far the most prominent local morbid condition.

**SYMPTOMS.**—This affection is characterised by red lines running in the course of the lymphatic vessels from some local sore or wound. The lines are at first tolerably sharply defined, and about a quarter of an inch in width, but after a short time they spread out and several may coalesce, forming a patch exactly resembling simple cutaneous erysipelas. There is slight œdema, some pain and stiffness, and acute tenderness on pressure. The lymphatic glands to which the vessels lead are swollen and tender. The constitutional symptoms are the same as in simple erysipelas.

**DIAGNOSIS.**—This affection can only be mistaken for phlebitis; but the diagnosis is easily made by observing the course of the lines, and by the absence of the knotted cord formed by the coagulation of the blood in an inflamed vein.

**TREATMENT.**—The treatment is the same as in simple erysipelas. The extract of belladonna and glycerine is especially useful in this form of erysipelatous inflammation.

**V. Erysipelatous Phlebitis.**—Inflammation of the superficial veins, rapidly spreading in the course of the circulation, accompanied by thrombosis, redness of the skin, and acute tenderness, has been supposed by some authors to be erysipelatous in character. The only evidence in favour of this view is that the invasion and the constitutional symptoms resemble those of erysipelas, and that the affection is not uncommon during epidemics of erysipelas. See VEINS, Diseases of.

Various other diseases have been classed as erysipelatous; the chief of these are whitlow, some forms of puerperal fever, and diffuse peritonitis after operations affecting the peritoneum; all these will be described elsewhere. Diffuse inflammation not infrequently occurs after punctures made to allow of the escape of the fluid in the dropsy of cardiac or of renal disease. That punctures made into feebly nourished tissues bathed in decomposable serous fluid should set up diffuse inflammation is not surprising, but evidence is wanting to prove that such inflammation is necessarily connected with erysipelas. MARCUS BECK.

**ERYTHEMA** (*έρυθρός*, red).—**SYNON.**: Rose-rash; Fr. *Erythème*; Ger. *Hautröthe*.

**DEFINITION.**—A non-infective superficial inflammation of the skin, the essential characteristic of which is redness, that disappears on pressure by the finger, reappearing when the pressure is removed. The hue may

vary from a bright rose to a dark blue red; it may or may not be accompanied by swelling; the part may be hotter than natural; and the appearance may present itself as spots, circumscribed or diffuse, or as wheals. It is sometimes attended by a sensation of slight burning or itching, but generally gives rise to no subjective symptoms. After it has disappeared the skin is either normal, or remains slightly pigmented, or desquamates. Generally there is an increase of temperature, with slight feverish symptoms. Erythema may be either *symptomatic* or *idiopathic*.

**Symptomatic Erythema.**—**ÆTIOLOGY AND VARIETIES.**—Erythema occurs in rare instances after the administration of drugs. Cases are recorded after the ingestion of arsenic, belladonna, chloral hydrate, copaiba, cubeb, digitalis, iodides, opium, quinine, salicylic acid, stramonium, strychnine, phenazone, and turpentine. The rash usually appears immediately after the absorption of the medicine into the circulation; after arsenic it appears at a later period. See **DRUG ERUPTIONS**.

Exposure to heat or cold, and contact with various acrid or poisonous substances, are also common causes of erythema. Friction and (in the absence of cleanliness) the secretions of the skin itself, may give rise to it, as when *erythema intertrigo* is produced between the scrotum and thighs by the irritation of profuse sweat and sebaceous secretions. The blush of shame or of anger is an erythema produced by the immediate action of the vaso-motor nervous system.

Variola, cholera, enteric fever, typhus, septicæmia, rheumatic fever, and various other less distinctly defined febrile conditions, are frequently accompanied during various stages of their course by a more or less generally diffused and mostly ephemeral form of erythema.

The *roseola infantilis* of authors is an erythema that accompanies intestinal disturbance, teething, and various other disordered conditions of the system in children. Its appearance may exactly simulate that of measles or scarlatina; but it differs from these in disappearing in less than twenty-four hours, and in leaving no desquamation behind it.

The erythema that accompanies smallpox—*roseola variolosa*—appears generally on the second day of the disease, either as a diffuse redness of the whole integument, or as bright red spots, which are seen first on the face and then on other parts of the body. It lasts from twelve to thirty-six hours, and disappears when the smallpox eruption begins to show itself. A special limited form of erythema has been observed on the second and third days of smallpox, extending from the hypogastrium down the front of the upper two-thirds of the thighs; the affected surface,

when the legs are closed, having the form of a triangle the base of which is across the lower part of the abdomen. This surface remains almost or entirely free from the various pustules, and many of the cases in which it is present end fatally.

From the third to the eighteenth day after vaccination, small or large erythematous patches—*roseola vaccina*—are sometimes seen, generally on the arms, but also on other parts of the body. They usually disappear within twenty-four hours, and leave neither desquamation nor pigmentation.

The forms of erythema mentioned above cannot be considered as being in themselves specific varieties of disease, and pathologically consist in a temporary injection of the capillary blood-vessels of the skin. They are to be distinguished from the erythemata that run a distinct course, terminating in pigmentation and desquamation, and in which the capillary injection is accompanied by exudation.

**Idiopathic Erythema.**—**I. Erythema multiforme.**—This form of idiopathic erythema is most commonly seen in spring and autumn, and is distinguished by its localisation. It begins on the backs of the hands and feet, and frequently is found in these situations only. In some cases it extends upwards to the shoulders and hips, and in very rare cases is also found on the trunk.

The appearance consists in flattened papules, from the size of a pea to that of a bean, of a dark blue or brown-red colour. They are surrounded on their first appearance by a red zone, which soon disappears, and the border of the papule then stands out in fuller relief. The mildest form of this disease consists in papules which disappear after a few days—*erythema papulatum vel tuberculatum*. Instead of thus disappearing it may spread outwards from the edge, and flatten and become pale in the centre, thus forming a red ring, the condition being known as *erythema annulare*. While the first circle persists, a second ring may form around it, and the circles may be constituted by small papules, forming the condition recognised as *erythema iris vel mamellatum*. Another stage may be reached by the enlarging circles meeting, and so forming segments of a circle, constituting the form known as *erythema gyratum vel marginatum*. In consequence of increased exudation erythema papulatum may assume the aspect of a wheal, forming *erythema urticatum* or *lichen urticatus*. This condition is attended with considerable itching; and, in consequence of scratching, the centre of the papular wheal is often covered by a minute bloody crust. The exudation may be sufficient to give the eruption the aspect of vesicles or bullæ, the so-called *erythema vesiculosum* and *erythema bullosum*. Concentric circles of vesicles produce the appearance called *herpes iris*.

At any of these stages the eruption may disappear. The sequelæ are slight pigmentation and desquamation.

The disease, whose different stages have received the several names above indicated, has been designated, on account of the various forms under which it is seen, *erythema exsudativum multifforme*. It is accompanied by a slight feeling of burning, or by very slight itching. In the majority of cases constitutional symptoms are either absent, or are so insignificant as not to excite attention. There are, however, cases in which the symptoms are as marked as those which precede and accompany an eruptive fever. The prodromal symptoms are usually pain in the back, head, limbs, and joints, with gastric disturbance, and sometimes a congested condition of the throat and fauces. In severe cases the prodromal period has been observed during four to six days; and amongst other symptoms sneezing, bleeding at the nose, laryngitis, bronchitis, intense sweating, mental disturbance, and fever have been observed. All these symptoms may become aggravated during the period of eruption. In well-marked cases the disease may last from a fortnight to a month, but in exceptional circumstances the symptoms may be prolonged by fresh outbreaks of eruption. Simultaneously with the eruption on the skin, red spots may appear on the mouth and pharynx, from which the epithelium quickly disappears, leaving the parts raw and painful. Cases are recorded in which symptoms of severe intestinal disturbance, shivering, high fever, intense inflammation and ulceration of the mucous membrane of the throat, severe mental depression, and a painful condition of the joints, have been present.

In some cases the erythema is punctiform, and so much resembles the appearance of scarlatina that authors have described an *erythema scarlatiniforme*. It is distinguished from scarlatina by the absence or very slight degree of fever. The fauces, although red, are not swollen. There is no characteristic appearance on the tongue; and the pulse is little affected. There are no sequelæ.

Hebra relates that in a woman who died whilst an eruption of *erythema gyratum* was on the skin, similar red rings were found in the small intestine. It is most common in adolescence, and is more frequent in males than in females.

II. *Erythema nodosum*.—This name is given to a disease characterised by the appearance, chiefly on the surface of the lower extremities, of pale red hemispherical or oval swellings. These vary in size from that of a pea to that of a hen's egg, and are painful on pressure. Fever is sometimes present.

The swellings are at first pale red with a

yellowish tinge, later dark red, and finally livid; after they disappear they leave behind them a yellow pigmentation similar to that which follows a contusion. The number of swellings may vary from a very few on the lower extremities to successive crops on different parts of the limbs and trunk. In the latter case the feverish symptoms are well-marked. The course of the disease is completed in from two to four weeks. The swellings never suppurate, never itch, are always painful, and the redness never spreads to the adjoining skin. This variety can occur in combination with the previously described forms of *erythema multifforme*.

*Erythema nodosum* is found to be so frequently associated with definite rheumatic symptoms, such as arthritis, sour sweats, sore-throat, endocarditis, and even myocarditis, that it may be considered very probable that the affection is allied with the rheumatic diathesis.

A case has been reported in which phlebitis leading to embolism has complicated the disease.

ÆTIOLOGY.—The cause of erythema nodosum is not definitely known, although, as we have remarked, it is frequently associated with rheumatism. Some authors favour the view that it may be considered as a typical angioneurosis, whilst others believe that it is always an infective constitutional disease. It may occur at every age, but generally from eighteen to thirty, and most frequently in women. It occurs at all seasons, and debility predisposes to attacks.

ANATOMICAL CHARACTERS.—The microscopical appearances are those of an inflammatory hyperæmia. Leucocytes are found around the blood-vessels, and there are extravasations of red corpuscles. There is also an effusion of serum between the cells of the epidermis.

PROGNOSIS.—The prognosis of the special forms of erythema—*multifforme* and *nodosum*—is usually favourable, but cases are reported in which death has been caused by visceral complications. It is assumed that in these exceptional cases both the skin-eruption and the visceral lesions are produced by some infective poison. Those varieties seen in the course of other diseases do not as a rule modify the prognosis of the particular disease which each accompanies.

TREATMENT.—The treatment of erythema consists in palliating the attendant symptoms. Dusting with flour, or the application of spirit-lotion, should be employed when productive of a sense of comfort to the patient. In *erythema nodosum* warm applications of infusion of poppies or chamomile are soothing; while aperients and, when fever is present, gentle diaphoretics may be given internally. In many such cases tonics, especially quinine, are required.

GEORGE THIN.

**ERYTHRASMA** (έρυθρός, red).—This is a chronic, very slowly developing, contagious, epiphytic disease of the skin, characterised by a very slight erythematous inflammation, which usually occupies the cruro-serotal or axillary regions, but is capable of wider generalisation; produced by the presence in the corneous layer of a remarkably minute fungus—the *microsporon minutissimum* (Bueckhardt and Von Bärensprung).

**DESCRIPTION.**—Erythrasma is little known, and generally confounded with eczema marginatum. Fairly common in men, although it occasions little discomfort, it is less frequent in women, in whom it may be found about the axillary or perigenital regions.

The patches are rounded, not marginate or sensibly raised, from  $\frac{3}{4}$  inch to  $1\frac{1}{2}$  inches or upwards in diameter, uniformly roughened, and coloured yellowish-red or brownish. The pruritus and inflammation are very slight.

There are abundant delicate mycelia and conidia present, forming a rich network round the cells. The fungus requires staining and high powers for its demonstration. It is said to occur normally on parts of the skin, but erythrasma has been inoculated by Köbner.

**TREATMENT.**—All parasiticide agents, such as iodine, resorcin, salicylic acid, and chrysarobin, capable of causing exfoliation, succeed in curing erythrasma. Relapses are apt to occur unless treatment is long-continued.

T. COLCOTT FOX.

**ESCHAROTICS** (ἐσχάρια, a slough).—**SYNON.**: Fr. *Escharotiques*; Ger. *Aetzmittel*.

**DEFINITION.**—Escharotics are substances that completely destroy the tissues to which they are applied, and produce a slough. They are distinguished from other caustics simply by the greater intensity of their action.

**ENUMERATION.**—The chief escharotics are: Red-hot metal, Sulphuric Acid, Nitric Acid, Caustic Potash, Chloride of Antimony, Chloride of Zinc, Acid Nitrate of Mercury, Bromine, Chromic Acid, and Lime. Weaker caustics are—Nitrate of Silver, Sulphate of Copper, Sulphate of Zinc, Iodine, Carbolic Acid, Arsenious Acid, Sulphide of Arsenic, and Dried Alum.

**ACTION.**—Escharotics combine with the tissues and destroy them. Around the part thus killed inflammation is set up, and the part is separated as a slough. Besides their local action, these agents act reflexly on other parts of the body through the nerves of the region to which they are applied.

**USES.**—Escharotics are employed, first, to destroy the virus in, and the tissues around, a poisoned wound, and thus prevent the absorption of the poison—for example, in bites by snakes or rabid animals, or in cases of inoculation with syphilis, or with animal-

poison in dissection or *post-mortem* wounds. Secondly, they are used to destroy unhealthy tissue, such as exuberant granulations, and to remove excrescences and morbid growths, as warts, condyloinata, nævi, polypi, hæmorrhoids, and cancer. Thirdly, they are used to open abscesses, especially those of the liver. For this purpose caustic potash is usually employed. Lastly, by means of escharotics it is usual to establish issues, and thus react beneficially on distant organs.

**EUTHANASIA** (εὖ, well; θάνατος, death).

**DEFINITION.**—Mental and physical distress too often attends the approach of death; and by the term 'euthanasia' we express the measures by which we alleviate or seek to remove this distress.

**IMPORTANCE OF EUTHANASIA.**—To procure euthanasia is of great moment to the patient, to the patient's friends, and to the practitioner.

It is the duty, and should be the constant aim, of every thoughtful practitioner to acquire the art of successfully smoothing the death-bed of his patient. He will thereby be enabled, when this is necessary, to relieve him of much of the attendant suffering, and to prevent many troubles individually of smaller moment, but collectively the source of much discomfort or distress. The friends' anxiety will be lightened by the relief afforded to the patient. Their own efforts in this direction are frequently unsuccessful; indeed may sometimes be prejudicial. The comfort of the dying is very often interfered with, and actual suffering induced, by the interference of well-meaning but inexperienced friends or relatives. Indeed they will sometimes question the action of the practitioner respecting the employment of a measure of which he may wish to avail himself, or they will administer food and stimulants to the patient in quantities which may be excessive or deficient or given at improper intervals. Death may thus be very often accelerated, and not without discomfort. To the practitioner himself the subject of euthanasia is one of great importance. He is involved in a position of grave responsibility, demanding the display of much tact and judgment, and one by which his professional

character will certainly, in part, be estimated. Much of his success will depend on his natural possession of these qualities, and to lay down any strict or rigid rules for his guidance is obviously impossible.

**THE MORBID STATES CALLING FOR EUTHANASIA.**—1. *Mental Condition.*—The question of dealing with the mental distress of the dying is one which only secondarily concerns the practitioner, and will therefore be noticed but briefly here. The most important point to be decided is: Should the practitioner be the medium of communicating to his patient the hopelessness of his case? Whenever possible, this painful duty should be relegated to the friends of the patient, who are always to be informed of the approach of death, in order that due attention may be paid to the affairs of the sick person, both spiritual and worldly. The practitioner should not hastily take on himself to tell him of the inevitable result of his illness. The patient may or may not desire to know the truth, and when it is communicated to him it is certain to affect his peace of mind in the one or in the other direction. Some welcome the announcement; whilst others are filled with dread. But it is a fact that the majority of persons seriously ill feel less on such matters than they would have felt in health: they 'mate and master,' as it were, 'the fear of death.' With many patients, not to know the truth respecting the danger which they are in, is itself a form of unhappiness which militates against the establishment of euthanasia. The practitioner should therefore most carefully study the individual case and the character of his patient. On the one hand he will exercise the greatest care not to falsely conceal their situation from the dying; on the other hand, he must keep in mind that a fatal termination is not always *certain*, and that in many cases the last chance of an over-sensitive patient may be destroyed by the prospect of problematical dangers (*see* DISEASE, Prognosis of). Good sense, kind feeling, tact, and experience, will prove of the greatest value in discharging this delicate duty as it comes before us in a general practice. *See* DEATH, Modes of.

2. *Bodily Conditions.*—The physical states which specially call for euthanasia are—pain; dyspnoea, cardiac distress, exhausting cough; laryngeal distress; difficult expectoration; restlessness and sleeplessness; thirst; hic-cough; abdominal distension; dropsy; bed-sores; and exhausting discharges. These, and a few of the general and therapeutic measures at our command which ought ever to be present to the mind of the practitioner for abolishing or mitigating sufferings incident to the dying state, will now be briefly touched upon.

The removal of *pain* is essential for the promotion of euthanasia, and no other remedy

is so successful for this purpose as opium or morphine cautiously administered. It is an adjunct of the greatest value to other measures, and, moreover, successfully combats the exhaustion and sinking sensations which, in certain cases, are a source of indescribable distress. Its anodyne effect is enhanced by its cardiac action. Its administration, however, often leads us into much fresh difficulty, by causing a dry tongue and distressing thirst; by arresting the excretions; in other instances by increasing the reluctance to take sustenance; or the presence of kidney-disease may prove a serious contra-indication to its employment.

The question as to the patient remaining out of bed pillowed up in a suitable chair will sometimes arise when *dyspnoea* and *flatulence* are urgent; and will demand much judgment and care. By rendering moist the air of the bedroom with the vapour of hot water in a bronchitis-kettle placed upon a fire (not over gas or spirit-lamp contrivances, which only tend to vitiate the atmosphere of the sick-chamber), we can often insure the relief of pulmonary distress. Uramic dyspnoea will call for the administration of nitroglycerine, nitrite of amyl, or sulphuric ether.

Painful *cardiac* palpitation, and its attendant distress, often derive relief from the administration of antispasmodics along with iodide of potassium, a belladonna plaster at the same time being applied over the præcordia. Digitalis, strophanthus, strychnine, or some of the other well-known excellent cardiac tonics, may also be resorted to with success.

One of the most distressing symptoms in the dying is the exhausting *cough* of phthisis, which greatly exhausts the patient. It may be combated by judicious nursing; by an acid linctus, with or without the addition of a little morphine; by a combination of respiratory sedatives; by the frequent administration of small quantities of alcoholic stimulants; or by hot or cold liquid nourishment. The *laryngeal distress* which frequently attends the final stage of phthisis will best be relieved by morphine insufflations, cocaine sprays, or recourse may be had to rectal alimentation. The loud, noisy, gurgling râles met with in the last phases of bronchitis and other conditions will call for change of posture and stimulants, although they are more distressing to the friends than a source of danger to the patient (*see* STERTOR). When the attempts at *expectoration* are difficult, measures must be employed which possess the power of diminishing the viscosity of the expectoration, or of stimulating the respiratory centre and the respiratory movements. *See* EXPECTORANTS.

The *restlessness* and tossing of the limbs, irregular sighing, with coincident *sleeplessness*, which so often attend the last days

of fatal illnesses, may sometimes be relieved by attention to the weight of the bedclothes, which can be conveniently reduced by employing a suitable cradle. The arrangement of the pillows and attention to the posture of the dying patient constantly tax the ingenuity and resource of the attendants. The temperature and ventilation of the sick-room are also of great importance in this respect, closeness and over-heating being zealously prevented, as well as crowding of the sick-chamber with anxious friends. The feet and legs ought to be frequently examined, and if chilled they should be warmed by a carefully applied foot-warmer. The unpleasant effects of cold sweats will also call for attention. The catheter will remove another often overlooked cause of inquietude—a distended bladder. By these and similar measures we may be able to counteract the cause or causes of insomnia, and thus secure for our patient a few precious hours of sleep.

*Thirst* is often a most distressing symptom. It may best be relieved with ice, or with teaspoonfuls of iced water or acidulated, unsweetened, cold black tea or coffee. But in this connexion let it be understood that we must be careful to avoid the popular mistake of forcing down liquids in cases where life is evidently fast ebbing away. Such a practice necessarily embarrasses respiration, and we have likewise to remember that at this time the act of deglutition very often is in abeyance. Death is occasionally accelerated by injudicious attempts to raise the patient, open his mouth, and administer food.

In the management of the dying we have always to contend with an enfeebled digestion. The *diet* in such cases should be one easy of assimilation. It not infrequently happens that the food given may be excessive or deficient in quantity, or that it is administered at irregular intervals, thereby causing much distress to the patient. Success in this direction depends solely on the tact of the nurse. Whilst in acute disease nothing conduces more to success than definite instructions as to the amount and kind of the food to be given, and the hours for its administration, it is impossible and inadvisable to observe these rigid rules in the feeding of the dying.

In conjunction with nourishment we can often remove much of the suffering by the judicious selection and administration of *alcoholic stimulants*. If the patient tires of one form of stimulant, another should be tried, provided we are careful to use only such as are easily digested and assimilated, and given in divided quantities. A combination of beef-tea, liquor strychninæ hydrochloratis, and brandy is often very acceptable, especially in bad cardiac cases. Another stimulant of extreme service is ether, which

particularly alleviates painful attacks of spasmodic breathing.

A sinapism to the epigastrium in conjunction with the internal use of a little ether and brandy, will frequently relieve that sometimes distressing symptom—hiccough.

Distressing *abdominal distension* must be relieved by the employment of turpentine stupes and by enemata containing some antispasmodic. *See* ENEMA.

The treatment of dropsy, abdominal distension, bed-sores, and exhausting discharges is dealt with in other parts of this work.

In addition to the conditions which call for euthanasia, it is clear that the severe dietetic restrictions which may have been enforced in a case of Bright's disease, diabetes, &c., ought to be reconsidered and removed when it becomes apparent that the patient's condition is absolutely hopeless. The wishes and suggestions of the patient may generally be acquiesced in, and they will prove a useful guide to the practitioner as to the line of action to pursue. It is often the wisest course to humour cravings. Seeming extravagances as to diet, if persistently asked for, had better be granted, especially when kind and gentle persuasion has failed to get the patient to waive his desire for them.

In addition to the means already mentioned, it need hardly be said that we still have all those measures which may be summed up in the expression 'perfect nursing,' which implies carrying out many details as well as exercising sympathy and tact—a nurse not overdrilled. A mere automaton thinks too much of her 'uniform' and of her 'duty.'

JOHN HAROLD.

**EVACUANTS** (*evacuo*, I empty).—

SYNON.: Fr. *Evacuants*; Ger. *Ausleerende Mittel*.

DEFINITION.—Medicines used to produce some evacuation from the body.

ENUMERATION.—The chief evacuants are: Sternutatories, Expectorants, Sialagogues, Emetics, Cholagogues, Purgatives, Diaphoretics, and Diuretics. *See* the several articles upon these subjects.

**EVIAN-LES-BAINS**, in Savoy, France.—Alkaline waters. *See* MINERAL WATERS.

**EXACERBATION** (*exacerbo*, I aggravate).—Increase in the severity of the symptoms of a disease. *See* DISEASE, Duration of.

**EXANTHEMA**; **EXANTHEMATA** (*ἐξ*, out; and *ἀνθῆω*, I blossom).  
SYNON.: Fr. *Exanthème*; Ger. *Ausschlag*.

DEFINITION.—A rash or eruption on the skin attending a specific fever. The specific fevers attended by rash. This term, once denoting any cutaneous eruption, is now restricted to the eruptive fevers called the *exanthemata*. The febrile rashes or exanthes

of local or individual origin — urticaria, erythema, and roseola—are not included with the true exanthemata, which are acute specific infectious diseases, namely, Typhus, Variola, Varicella, Morbilli, Rubella, Dengue, Scarlet Fever, Typhoid or Enteric Fever, and perhaps Erysipelas. As the leading features of these diseases will be discussed under their several heads, it is only necessary further to notice certain less defined and regular eruptions associated with fever.

All the exanthemata are attended with fever and enlargement of the lymphatic glands. Convulsions in children may occur with the first fever; in some of the diseases before the rash appears.

*Typhus*.—The mulberry rash appears suddenly on the fourth and fifth days of illness as a dull red mottling of irregular, persistent, non-elevated spots; the fever is high at the commencement, and continues to be so after the rash is fully developed.

*Typhoid*.—In typhoid or enteric fever the small, raised rose-spots do not appear till the second week of fever; sparsely scattered on the trunk, they fade on pressure, disappearing in three or four days, while new spots arise.

*Smallpox*.—Marked fever of sudden ingress occurs two days before the raised eruption. Sometimes a rose-rash first appears, but the severe symptoms begin a full day before this, and not more than two days before the characteristic spots. The cervical glands are enlarged.

*Varicella*.—The eruption begins on the first day of illness, with slight fever, increasing as fresh spots appear. The fever may be high and come on suddenly, but enlarged cervical glands and spots somewhere are always to be found at the same time.

*Measles*.—Three days of fever and catarrh, with palpable enlargement of the cervical glands, precede the rash; there is then sudden increase of fever, subsiding while the rash is at its height.

*Rubella; Rubeola sine catarrho*.—The rash appears within a few hours of the first feeling of illness, which is slight and soon over. The rash is at first spotted rather than finely diffused. By the time it is fully out the fever has subsided, but the enlarged cervical glands which marked the ingress always remain to indicate a specific disease. Fine desquamation rarely follows, and there is no albuminuria. Rubella spreads by direct infection, the incubation being from two to three weeks. This long period of incubation causes the source of infection to be often overlooked, and even the possibility of it to be denied. When carried to a family or school either an unnecessary alarm of measles is raised; or contagion is denied, and the next sufferers are said to have a rose-rash from heat, or from irritation of the stomach.

*Dengue*.—Widely spread in Africa, the warmer parts of America, and both the Indies,

dengue may possibly be limited to hot climates; its presence with us is as yet undetermined. The rash is at first discrete, like that of measles, but follows soon after infection; and the disease in its general course is allied to influenza.

*Scarlet Fever*.—The finely diffused redness is found on the skin and in the mouth and throat often within a few hours of the sudden ingress of fever. The fever increases with the development of the rash, both persisting for several days. Often the throat is first complained of; the glands at the angle of the jaw are full and tender; the tongue presents prominent red papillæ projecting through the white fur. The skin is not swollen as in erysipelas, nor the redness so circumscribed; the throat also is redder; the cervical glands are enlarged in both. Surgical scarlatina is often declared three or four days after operations; the rash of septicæmia at a later period.

*Epidemic Roseola*.—This is a name for röteln; also for a rash having such relation to scarlet fever as rubella to measles, but with slender claim to autonomy. Mild cases of scarlet fever often begin with a finely diffused redness shortly after some feeling of faintness or giddiness, and an incubation of from three days to a week; sometimes albuminuria occurs as an early symptom. The finely diffused rash, enlarged cervical glands, and slight sore-throat, even with very little elevation of temperature, raise the suspicion of scarlet fever; should albuminuria follow, or any shredly desquamation of the hands and feet, no uncertainty remains. Scarlet fever so modified often spreads and gives rise to the severer forms of the disease, when it has been called only rose-rash or roseola; the use of these terms without a distinctive qualification always leaves a doubt as to the completeness and safety of the diagnosis.

*Erythema*.—Erythema comes nearest to these cases in appearance—so near as often to be spoken of as recurrent scarlet fever or erysipelas, but there is no enlargement of the cervical glands in erythema, and so little fever that the temperature of the reddened skin is barely elevated above the normal. Since Fuller's *Exanthematologia* this kind of flush passes under different names of roseola, according to the variations in shape of the red patches, or the seasons of the year at which they occur.

*Erythema nodosum*.—This disease is often preceded by slight fever for a day or two, which may reach 102° F., but subsides as the red swellings appear. Locally there is little or no elevation of temperature, even when the tender part feels hot.

*Exanthematous Roseola*.—This affection, occurring in the course of other specific diseases, is distinguished from the roseola which depends on nerve-irritation, such as that from acrid ingesta, by the presence either of high

fever, or of glandular enlargement, or of both, as when it precedes the true variolous eruption. During enteric fever this form of roseola may occur quite independently of the special lenticular rose-spots.

An eruption of this kind is not infrequent in the early stages of diphtheria, sometimes as a diffused rash limited to certain parts of the chest and body, or as discrete spots on the limbs and back of the hands and feet. Influenza, and some forms of catarrh, winter 'colds,' or summer diarrhoea as noticed by Bateman, may present various kinds of roseola on the back, shoulders, and chest; the cervical glands are perceptibly enlarged, though there may be little fever. In these cases it is not the roseola, but the specific disease on which it depends, that might, without precautions, be communicated to others.

*Syphilitic Roseola.*—A special roseola marks the secondary stage of syphilis; in appearance it resembles the rash of measles. So does the *roseola ab ingestis* when produced by cubebs, but this has neither fever nor glandular enlargement.

The absence of fever from the roseola after vaccination refers this form of eruption, like that occurring from dentition, to the class of rashes from nerve-irritation. *Vaccinia* is itself an exanthem in the wider definition of the term, reproduced after a definite period of incubation by inoculating a special contagium. Wanting this character, the different forms of herpes are excluded, unless resulting from a general febrile disturbance; though inoculable, ecthyma and impetigo are local affections not belonging to the exanthemata.

WILLIAM SQUIRE.

**EXCITANTS** (*excito*, I excite).—It seems hardly necessary to give any special consideration to this therapeutical class, as all that may be said on the subject ranges itself with greater propriety under the heading **STIMULANTS**. Stimulation is, in fact, a degree of excitement; and it is only when its effects are more vigorously pushed, that we obtain that inebriation or exhilaration which is so commonly observed to follow the use of alcohol, ether, and the anæsthetic vapours. See **STIMULANTS**.

ROBERT FARQUHARSON.

**EXCITING CAUSES.**—See **DISEASE**, Causes of.

**EXCITO-MOTOR DISORDERS.**—See **REFLEX DISORDERS**.

**EXCORIATION** (*ex*, from; and *corium*, the skin).—The superficial destruction of a portion of the skin or mucous membrane.

**EXERCISE.**—**DEFINITION.**—In its widest and most correct signification, exercise is the setting in motion any active body; and when the term is used in a physiological connection, it may refer to the functional

activity of any of the organs, whether muscular, nervous, nutritive, secretory, or reproductive. In this very comprehensive sense, the subject of exercise includes a large portion both of hygiene and of therapeutics. The popular signification of exercise is, however, much more limited than the preceding, having reference only to the muscles directly, and to the parts called into play through the same—especially the circulatory and respiratory systems.

Whether in its wider or in its narrower sense, exercise has several important relations to Medicine. 1. It is essential to the preservation of health (see **PERSONAL HEALTH**). 2. It has to be regarded as frequently associated with the causation of disease (see **DISEASE**, Causes of). 3. Exercise is a most rational and successful means of treatment in certain disorders and diseases (see **MOVEMENT**, Therapeutical Uses of). 4. Exercise is often abused; and excessive indulgence in some forms of it gives rise to serious consequences. The present article will be devoted to the consideration of exercise in the last-named aspect only; and the subject will be discussed according to the more limited and popular definition of the term.

**Abuse of Exercise.**—From the moment an infant is born until the end of life, exercise, duly apportioned to rest, is the normal state of existence; and whilst continued overstrain of any portion of the human machine is the forerunner of disease, so, on the other hand, is equally, if not more so, that want of exercise which induces wasting and degeneration.

**PRINCIPLES.**—The late Dr. Parkes, in his *Practical Hygiene*, has given a very complete statement of the results of the investigations of himself and others on the changes effected by the stimulus of muscular exercise on the various organs and tissues of the body, from which he has drawn the following conclusions:—

'The main effect of exercise is to increase the oxidation of carbon, perhaps also of hydrogen. It also eliminates water from the body, and this action continues—as seen from Pettenkofer and Voit's experiments—for some time; after exercise the body is therefore poorer in water, especially of the blood; it increases the rapidity of circulation everywhere, as well as the pressure on the vessels, and therefore it causes in all organs a more rapid outflow of plasma and a more active absorption—in other words, a quicker renewal.

'In this way, also, it removes the product of their action which accumulates in organs; and restores the power of action to the various parts of the body. It increases the outflow of warmth from the body by increasing perspiration. It therefore strengthens all parts. It must be combined with increased supply both of nitrogen and carbon (the

latter possibly in the form of fat), otherwise the absorption of oxygen, the molecular changes in the nitrogenous tissues, and the elimination of carbon, will be checked. There must also be an increased supply of salts, certainly of chloride of sodium, probably of potassium phosphate and chloride. There must be proper intervals of rest, or the store of oxygen, and of the material in the muscles which is to be metamorphosed during contraction, cannot take place. The integrity and perfect freedom of action both of the heart and lungs is essential, otherwise neither absorption of oxygen, nor elimination of carbon, can go on, nor can the necessary increased supply of blood be conveyed to the acting muscles without injury.'

The proper amount of exercise requisite for health is difficult to determine, in consequence of the varied constitutions of individuals. It may, however, be accepted that whilst in youth the great spirit of emulation tends to an overstrain of mind or body, so, as life advances, one or other or both are liable to be allowed to pass into a state of unhealthy inactivity.

Since the more general practice of gymnastics in this country, and the stimulus that has been given to aquatic exercises by our University competitions, great attention has been drawn to the effect of bodily exercise on health, and more especially with regard to the heart and lungs, these being the organs upon which its influence is most immediately exerted.

*Prolonged and Excessive Exercise.*—Of all exercises, rowing is the one which is generally accepted as the best variety to select, if we are to endeavour by a consideration of its influence upon those who practise it to form an estimate of the effect of a continuous strain on the circulation and respiration; yet the difficulty of procuring trustworthy evidence on such a subject is extreme. Dr. Morgan, in his *University Oars*, by collecting the various experiences of nearly all the men who rowed in the University races from 1829 to 1869, has obtained about the most accurate testimony available in regard to one aspect of the subject. These men are unanimous in their belief that they experienced no injury from the great strain they underwent in their youth. But it must be borne in mind that they were the picked athletes of their colleges, men with large frames and full chests, typical specimens of health, capable of undergoing very prolonged exertion with but passing fatigue, and to whom no permanent injury could be anticipated, after careful training, from an exceptional display of strength. Such evidence affords no clue to the effect of the strain imposed on the heart by the two hundred or more of each University, who annually use the utmost exertion to belong to the chosen few, and many of whom, unguided in their

violent efforts to achieve success, have in after-life to pay the penalty of allowing mere feeling or the spirit of emulation to overrule their reason.

*Exercise under Unnatural Conditions.*—But it is not only the case that exercise which is excessive or too prolonged proves highly deleterious; even a moderate amount of exercise under unnatural conditions may prove equally harmful. Thus the young soldier of light frame, with irritable palpitating heart, who has broken down in his preliminary training, is a marked and good example of the early injurious effect of overstrain of the heart, under the impediments caused by tight clothing and accoutrements to the free expansion of his chest. When at rest he feels perfectly well, and has little or no sensation of throbbing in his chest. So soon, however, as he puts on his tunic and accoutrements, and begins his drill, throbbing occurs with more or less violence, accompanied with a feeling of oppression, and with difficulty of breathing, and this being followed by a sensation of faintness, sickness, or dizziness, he has to fall out of the ranks. At first the condition of the heart is one purely of functional disturbance, which, though rendering him unfit for the duties of a soldier, does not interfere with his gaining his livelihood as a civilian.

This functional derangement of the heart, which is readily shown by the diastolicism in the sphygmographic tracing of the radial pulse when auscultation can detect little or no change in the heart-sounds, is frequently found in those youths of delicate frame in our schools and colleges, who, 'breaking down' in attempting feats of strength or in the preliminary training, experience no ill-effects in the ordinary avocations of after-life from that overstrain of heart which, if neglected, would be apt to lead to graver forms of heart-disease.

Whether it be by sudden or prolonged violent exertion, by rowing, or by running, or by the many other severe exercises of the body entailed by labour or pleasure, there can be no doubt that the heart and lungs have at times an inordinate amount of strain forced upon them, which, in a state of health, or under favourable circumstances, they may reasonably be expected to bear with no more injury than temporary distress, and that this capability to bear strain is greatly enhanced by careful training.

It is customary for the healthy boy, however, owing to the character of his amusements, always to be in training, so far as his body is concerned, and with very little supervision he ought to suffer no harm from sudden and exceptional strains. But it is very different with men who have settled down into the real business of life, who, during their nominal periods of rest from their daily labours, undertake violent exercises without

any preliminary training, and thus throw such an unexpected strain on the heart and great blood-vessels, that instead of mere functional disturbance, as in early life, they sow the seeds of organic disease. Such being the case, how much more injurious must sudden overstrain be to a heart already weakened by disease? There is often found amongst men a great aversion to having their hearts examined, and when disease is discovered it is sometimes considered of questionable advantage to inform the sufferer of his condition; but this is a mistake, for from want of knowledge of his state he may, by unnecessary strain, rapidly aggravate it, and thus shorten a life which might otherwise have been much prolonged.

The purport of these observations is thus to point out that: First, whereas exercise is necessary to preserve our bodies in a proper state of healthy activity, its tendency, when carried to extremes, is to set up organic lesions. Secondly, that as in some athletic competitions a very great strain is thrown upon the thoracic organs, it is essential that no boys of delicate frame should be allowed to take part in them, or in the preliminary training, excepting under careful medical supervision. And, thirdly, that in manhood no violent competition should be undertaken, which would throw a great strain upon the thoracic organs, without their being previously examined and pronounced sound, nor until their full powers have been brought into play by careful preliminary training.

A. B. R. MYERS.

**EXFOLIATION** (*ex*, from; and *folium*, a leaf).—The separation of a portion of dead bone or cartilage from the living tissue, in the form of layers (*see* BONE, Diseases of). The term is also applied to the separation of a false membrane, which has been mistaken for the whole mucous lining of the bladder or uterus. *See* BLADDER, Diseases of.

**EXHAUSTION** (*ex*, from; and *haurio*, I draw out).

**DEFINITION.**—Exhaustion is a phenomenon which all irritable tissues can be made to manifest, and consists in a failure to respond to stimulation. Exhaustion of muscle and nerve is brought about by excessive, quickly repeated, or continuous stimulation. It is favoured by cutting off, or by an alteration in the quality of, the blood-supply; by previous insufficient exercise of function; by exposure to extremes of temperature; by an insufficient supply of oxygen; by an excessive supply of carbonic acid; and by exposure to certain toxic agents. These facts, which have been established by physiological experiments, are fully borne out by clinical experience.

Exhaustion may be *general* or *local*.

**1. General Exhaustion.**—General ex-

haustion is brought about by over-work, whether physical or mental, and especially by unremitting and monotonous duties which keep the same paths of action in a state of constant activity. It is not often, if ever, that any permanent harm is produced in a healthy man by mere physical labour, however great; but excessive mental labour, especially if it be monotonous, is certainly capable of permanently damaging the nervous tissues. When in addition to hard mental work, which is performed voluntarily, some constant stimulus, which cannot be arrested, unceasingly works upon the brain, exhaustion quickly results; as when, for example, a man who is harassed by trying to earn sufficient for his family meets with some shock to his nervous system (such as a railway accident, the sudden death of a dear relative, or a severe money loss) which haunts him like a spectre day and night, robs him of his rest, and deprives him of his appetite. General exhaustion is favoured by all conditions which give rise to anæmia or faulty nutrition, such as hæmorrhage, prolonged pyrexia, inadequate diet, persistent morbid discharges, or venereal excess; by the retention in the tissues of the products of their activity, which is favoured by working in a foul atmosphere, or by derangement of the excreting functions; by exposure to extremes of temperature; and by a previous condition of excessive slothfulness. General exhaustion may occasionally be suddenly induced by physical causes, such as a severe injury (collapse from shock), or psychological causes, such as fright.

**SYMPTOMS.**—The symptoms of general exhaustion are: 1. Loss of sleeping power, persistent dreaming, talking in the sleep, and somnambulism. The patient may wake in the morning feeling totally unrefreshed. 2. Incapacity for work, and inability to seriously apply the mind to one subject for any length of time. 3. Headache, and a feeling of oppression in the head. 4. Languor and general lassitude. 5. A rapid feeble pulse. 6. An anxious expression of face; and (as stated by Dr. George Johnson) a contracted and sluggish pupil. In addition to these we may get tremor, delirium, hypochondriasis, hysteria, epilepsy, chorea, mania, and general paralysis. Two instances have come within the writer's knowledge of transient hemiplegic symptoms having been induced by excessive application to literary work. The digestion is often deranged, and functional disturbance of the heart is common. Occasionally the urine is altered in quality, and may contain alkaline phosphates or sugar. More rarely it manifests excessive acidity.

**2. Local Exhaustion.**—Local exhaustion is the result of excessive local stimulation, and it is particularly liable to occur as a prominent symptom in patients who are suffering from general exhaustion. The loss

of power in the rectum which results from the excessive use of purgatives; the failure of the uterus in cases of protracted labour; and the failure of the voluntary muscles which occurs in those professional ailments of which 'writer's cramp' is the type, may be taken as examples of local exhaustion.

**TREATMENT.**—In the treatment of exhaustion the main indications are to lighten the labour, and obtain rest. In cases of general exhaustion it is often advisable to administer narcotics, such as opium, chloral, sulphonal, or bromide of potassium; and it will be generally found that, when once refreshing sleep has been established, the more aggravated symptoms will subside. Fresh air and a good diet are most necessary. Stimulants must be used with great caution, for it is clearly not desirable to goad the exhausted organs into further action, although it may be necessary to employ stimulants to give temporary power while the faculty of sleeping is being re-established. All causes of anæmia must be removed. When recovery is established, the patient must be encouraged to relieve the monotony of his life by some pursuit which should be, as it were, the complement of his ordinary occupation. Thus the headworker should endeavour to amuse himself in his leisure hours by gentle out-door exercise, by music or painting, or by practising some handicraft. See **DEBILITY**; and **FATIGUE**.  
G. V. POORE.

**EXOMPHALOS** (ἐξ, out; and ὀμφαλός, the navel).—A term applied to umbilical hernia. See **HERNIA**.

**EXOPHTHALMIC GOÏTRE** (ἐξ, out; ὀφθαλμός, the eye; and *guttur*, the throat).—**SYNON.**: Graves's Disease: Basedow's Disease; Fr. *Maladie de Graves*; *Goitre exophthalmique*; Ger. *Glotzaugen-kropf*; *Basedow'sche Krankheit*.

**DEFINITION.**—Enlargement with vascular turgescence of the thyroid gland, accompanied by protrusion of the eyeballs, breathlessness, palpitation, tachycardia, and anæmia.

**ÆTIOLOGY.**—This disease is comparatively rare in men. It occurs most frequently in women between the ages of twenty and thirty, but is met with amongst older persons. Patients suffering from it often belong to the so-called nervous diathesis. Its occurrence is often preceded by menstrual disturbance and anæmia. Sometimes no exciting cause can be discovered, but in many cases it comes on after violent nervous excitement, sometimes after acute disease.

**SYMPTOMS.**—Before exophthalmic goitre makes its appearance, alterations in temper are frequently observed, the patient becoming irritable and depressed. Functional disturbances of the circulation and heart occur at frequent intervals, the heart palpitating,

the face flushing, and a sensation of fullness being felt in the head, eyes, and throat. The palpitation increases, the eyes become prominent, and a visible swelling appears in connexion with the thyroid gland. The eyes are lustrous and projecting, and there is frequently a slight loss of co-ordination between their movements and those of the eyelids, so that when the eyes are quickly cast down the eyelids follow them so slowly that a white ring of sclerotic may be noticed between the iris and the lower margin of the upper eyelid. Usually there is no disturbance of vision. The exophthalmos is most marked during emotional excitement and at the menstrual period, and at these times the patient suffers from an increased feeling of fullness in the eyeballs. Sometimes the projection of the eyeballs is so great that the lids do not perfectly cover them, and inflammation and ulceration may consequently occur. The thyroid is generally unequally enlarged. Its size varies from time to time, increasing, like the protrusion of the eyeballs, with emotion. It is soft and elastic, and pulsates, so that it has sometimes been mistaken for aneurysm. The palpitation of the heart is generally noticed before either the exophthalmos or enlargement of the thyroid, and is the first symptom to attract the patient's attention. It is increased by emotion or exertion; and the violent cardiac action frequently produces a prominence of the præcordial region. The cardiac pulsations are rapid, and sometimes irregular. The cardiac sounds are loud; and a soft, systolic bellows-murmur is frequently audible at the base, and in the large arteries. The carotids are sometimes, but not always, dilated. The circulation appears to be rapid, the veins filling quickly when emptied, and pulsation being felt even in small arteries. The temperature is frequently high. There is a feeling of general debility. The digestion is sometimes normal, at other times the appetite is diminished or capricious, and diarrhoea may occur. The swelling of the neck may give rise to a feeling of difficulty of breathing; and the voice sometimes becomes altered and hoarse, or may be lost entirely. The course of the disease varies considerably: it may sometimes go on increasing for several months, then it becomes stationary for one or two years, and afterwards begins to decline. The temper improves, the appetite increases, and menstruation frequently is re-established. The palpitation, enlargement of the thyroid, and prominence of the eyes gradually diminish, although they rarely disappear completely. Death may occur from intercurrent disease, from organic cardiac lesions, from uncontrollable diarrhoea, or from gradual wasting. Danger is also said to arise from pressure on the trachea by the enlarged thyroid.

**PATHOLOGY.**—The protrusion of the eye-

balls is due either to dilatation of the vessels in the orbit, or to contraction of the involuntary muscular fibres in the orbital membrane which covers the speno-maxillary fissure, or possibly to both causes combined. The enlargement of the thyroid is due to dilatation of the vessels of the gland. After the disease has lasted some time, increased formation of tissue in the thyroid gland may occur. Palpitation of the heart is probably due to stimulation of the accelerating cardiac nerves; and this, as well as the alteration in the nerves of the orbit and thyroid, has been ascribed to disease of the lower cervical sympathetic ganglia, in which increased connective tissue and diminution of ganglionic cells have been observed.

**DIAGNOSIS.**—When the three leading symptoms are present, it is impossible to confound exophthalmic goitre with any other disease. The enlargement of the thyroid is distinguished in this disease from that of cystic goitre by its greater elasticity, by its paroxysmal enlargement, and by its pulsation. The exophthalmos is distinguished from that due to disease of the orbit or cranium by being equal in both eyes, and by the absence of squint. It is distinguished from prominence due to cardiac disease by the lustrous appearance of the eye; from hydrophthalmia by the natural condition of the pupil; and from the prominence which may occur in myopia by the vision being natural, and by the paroxysmal increase of the prominence in exophthalmic goitre.

**PROGNOSIS.**—This must be guarded, the disease not being very amenable to treatment, and very rarely disappearing altogether, although after continuing for some years it may gradually improve.

**TREATMENT.**—The treatment of exophthalmic goitre chiefly consists in securing fresh air, gentle exercise, the avoidance of the least fatigue or emotional disturbance, and careful diet. Iron is sometimes useful, the milder forms, such as the tartarated iron or citrate of iron and ammonia, being preferable to the more powerful preparations. The writer believes he has seen much improvement from saccharated solution of lime. Quinine, alone or in combination with digitalis—and perhaps with belladonna—often produces good results. Digitalis and strophanthus are occasionally, but not always, useful. Aloes and myrrh may be employed to keep the bowels open. Galvanism to the neck has sometimes been productive of benefit, one pole being placed on the nape of the neck and the other along the sides of the thyroid tumour. When the eyeballs are so prominent as to become liable to inflammation and ulceration, care must be taken, by means of a shade, to protect them from irritation; and if this should prove unavailing, the inflammation must be treated by appropriate remedies.

T. LAUDER BRUNTON.

**EXOSTOSIS** (ἐξ, out of; and ὄσσειον, a bone).—A bony outgrowth from any part of the skeleton. See BONE, Diseases of.

**EXPECTANT ATTENTION.**—An important mental state. See MESMERISM.

**EXPECTORANTS** (ex, out of; and *pectus*, the chest).—**SYNON.**: Fr. *Expectorants*; Ger. *Auswurfsmitteln*.

**DEFINITION.**—Medicines which facilitate the removal of secretions from the air-passages.

**ENUMERATION.**—The leading expectorants are:—(A) Ipecacuanha, Antimony, Apomorphine, and Iodide of Potassium; Chlorides of Potassium, Sodium, and Ammonium; and Inhalation of Steam. (B) Squill, Senega, Benzoin, Benzoic Acid, Benzoate of Ammonium; Myrrh, Storax, Balsam of Tolu, Balsam of Peru, Ammoniacum, Galbanum, Asafœtida, Anise, Fennel; Larch Bark, Tar, Terebene, Copaiba; Vapour of Chlorine, Iodine, Ammonia, Creasote, and Carbolic Acid. (C) Ammonia, Carbonate of Ammonium, Strychnine, Nux Vomica, and Belladonna.

**ACTION.**—The mode of action of expectorants is not well understood, and any explanation of it in the present state of our knowledge can only be regarded as provisional. Expectorants may be divided into two classes—(1) Those which modify the nature of the secretions from the respiratory passages; and (2) those which modify the respiratory movements by which the secretions are expelled. In considering the mode of action of the first class it must be remembered that the secretions from the respiratory passages depend, like many other secretions, on two factors, the *direct* influence of the *nerves* upon the secreting structures, and the *amount of blood* supplied to them. Each of these two factors may be influenced to a different extent by various drugs. As has already been said, the exact action of each cannot be determined at present, but the first class of expectorants may be subdivided into two divisions which are distinguished in the foregoing enumeration as A and B. The division A rather diminish than increase the activity of the circulation, and are therefore called *sedative* expectorants. The division B somewhat increase the circulation, and are called *stimulating* expectorants. Those comprised under C *stimulate the respiratory centre* in the medulla oblongata, and increase the respiratory movements.

**USES.**—*Sedative expectorants* (class A) are useful when there is congestion of the respiratory passages, with very scanty, tough expectoration, as in commencing bronchitis. In such circumstances, when dry rhonchi are heard abundantly, with few or no moist râles, the patient often coughs until quite exhausted, bringing up scarcely anything. The administration of sedative expectorants renders the

secretion from the respiratory passages more fluid, abundant, and easy to expectorate. When these expectorants do not succeed in ordinary doses, their action may be much assisted by the administration of a purgative, or, still better, by giving either ipecacuanha or tartar emetic in such a large dose as to produce sickness and vomiting. When the distress of the patient is great, the abstraction of a small quantity of blood by cupping or by venesection may give great relief. The inhalation of steam alone is also beneficial, and the air of the patient's chamber should be kept warm and moist.

*Stimulating expectorants* (class B) do more harm than good when administered in the conditions just described, but are beneficial when the acute symptoms have passed off. When this is the case, but the expectoration is tough and somewhat scanty, squill is a useful expectorant; but when the expectoration is abundant, benzoin, balsams or ammoniacum would be preferable. In chronic bronchitis, inhalations of ammonia, chlorine, iodine, creasote, carbolic acid, eucalyptus, or pine oil are useful. When the expectoration is foetid, chlorine, iodine, and carbolic acid inhalations are best.

*The expectorants which act on the respiratory movements* (class C) are useful in cases of debility, as they stimulate the respiratory nervous centre in the medulla oblongata, as well as assist the failing circulation. They may be advantageously combined with stimulating expectorants, such as squill or benzoin, according to the nature of the secretion.

T. LAUDER BRUNTON.

**EXPECTORATION** (*ex*, out of; and *pectus*, the chest).

**DEFINITION.**—This word, which strictly means the act of expelling anything from the chest, is usually applied to the matter so expelled, which is also called *sputum* or *phlegm*.

**THE ACT OF EXPECTORATION.**—The smaller bronchial tubes are kept free from obstruction by the action of ciliated epithelium. The area of the smaller tubes being greater than that of their trunks, the air passes more forcibly through the latter, and so tends, even in natural breathing, to carry speedily away any accumulated secretion. The forcible acts of coughing (*see* COUGH) and 'hawking' increase the natural force and fulness of the expiratory effort, and clear the air-passages; the repeated closure of the glottis in coughing increases still further the expulsive effect, by causing the air to escape in sudden jerks. If the glottis cannot close in consequence of laryngeal disease, the act of expectoration becomes painful and difficult. Efforts at expectoration are also laboured and futile if the power to take a deep inspiration is lost in consequence of emphysema or muscular weakness.

Inability to expectorate is often the immediate cause of death, the 'suffocative catarrh' of the dying being another name for accumulation of phlegm which the patient is powerless to remove. By teaching the patient 'how to expectorate,' by the administration of a timely stimulant or a quickly acting emetic, or by change of posture, life may in such a case be prolonged. Should the sufferer be allowed to get flurried, the breathing becomes more and more shallow, and deep inspiration and free expectoration are impossible. If, however, the patient can be induced to breathe calmly and deeply, to assume a more easy posture, and to swallow a mixture of ammonia with ether, the breathing gradually becomes less shallow and rapid, air enters the deeper parts of the lung, and power is gained to evacuate the accumulated secretion (*see* STERTOR). The act of expectoration is, as a rule, most easy in that posture in which respiration is most free. Sometimes when the secretion comes mainly from one lung, the aid of gravitation may be called in to empty the obstructed tubes.

**CHARACTERS AND VARIETIES.**—Before auscultation was practised, diagnosis was often based on the character of the expectoration, unwarrantable importance having been attached to the distinction between pus and mucus, on the assumption that pus was diagnostic of phthisis. At the present time we are apt to lose much useful information by falling into the opposite error.

In health, the secretion from the mucous membrane of the air-tubes is a transparent, colourless, slightly glutinous liquid, like thin mucilage; it contains mucin, a varying quantity of saline matter, and water.

The saline matter is abundant in the transparent viscid expectoration, deficient in the opaque and less tenacious kind, least in that which is actually purulent.

The ordinary mucous secretion is increased in quantity and viscosity as a result of simple catarrhal inflammation of the bronchial membrane. When bronchitis has existed for some days, a change occurs in the character of the secretion; instead of being transparent and viscid, it becomes semi-transparent and then opaque, the colour changing to a yellow or greenish hue.

The sputum becomes frothy from the admixture of air; and rusty or prune-juice-coloured if the inflammatory action extends to the ultimate bronchial ramifications, and is of so intense a kind as to allow of oozing from the capillary vessels.

Fibrinous moulds of the bronchial tubes, or chalky masses consisting of inspissated and calcified cheesy matter, are not infrequently expectorated.

The dark grey or blackish stain often seen in expectoration may be derived from carbon in the atmosphere; or, if it fade on the addition of nitric acid, it may be due to pulmo-

nary pigment formed under slight irritation.

The expectoration may afford important aid in diagnosis, as may be illustrated by the following examples: If a person with severe chest-complaint coughs frequently and spits only frothy salivary fluid, we may suspect pleurisy. If the fluid is glairy, like white of egg, we may suspect bronchitis. If it has a rusty tinge and resembles thick gum-water coloured with blood, we are not likely to err in recording pneumonia. If there is a sudden gush of foetid pus we may diagnose abscess in the lung or an empyema.

Purulent expectoration may occur in bronchitis as well as in phthisis; but if long continued, and unaccompanied by distinct rhonchus, it almost always comes from a vomica. The excessively offensive expectoration of pulmonary gangrene, and that arising from a bronchiectatic sacculæ, are diagnostic of the affections from which they spring.

In phthisis the sputum is at first salivary or frothy, the result of irritation; then viscous, indicative of more confirmed affection of the mucous membrane; and subsequently dotted and streaked with blood. Whitish opaque spots, giving a pearly aspect to the expectoration, next appear; these enlarge, become flocculent and ultimately nummular, being fissured and moulded in a cavity. As the disease advances and involves both lungs, the expectoration is entirely purulent, and shortly before death is often surrounded with a pinkish halo. On placing under the microscope one of the small pearly points described, masses consisting of several air-cells choked with granules, or mere fragments of elastic tissue may occasionally be seen. By the addition of acetic acid the sputa may be rendered transparent, and the elastic tissue is then, if present, more certainly detected; but practically the experienced eye is the best guide in the selection of those small pin-head flocculi of expectoration, in which the microscopic particles of lung-tissue are to be detected.

The microscope may also be helpful by indicating, from the character of the cells, the part of the respiratory tract involved, and the degree of disease existing. (For the detection of tubercle bacilli, a point of great practical importance, see PHTHISIS; and SPUTUM, Examination of.) The existence of cancer of the lung may sometimes be detected by a microscopical examination of the expectoration.

**TREATMENT.**—In treatment, much may be gained by study of the expectoration. The cough may often be relieved, and the dyspnoea and other symptoms removed, by effecting an alteration in the nature of the secretion.

If by the frothy character of the sputa congestive disorder is indicated, this may be met by the application of warm poultices,

turpentine stupes, or hot flannels externally; and by such means as are calculated to reduce fever and irritability, namely, the administration of salines with antimony or aconite. If the expectoration is too viscid and glutinous for easy removal, lemon-juice, liquor potassæ, soda, or various inhalations give relief, by lessening the tenacity of the secretion; or the change from tenacious and transparent to opaque, less adhesive secretion may be hastened by giving iodide of potassium with a few drops of antimonial wine.

When muco-purulent secretion is established and shows no sign of diminution, the use of senega and of the gum-resins is indicated; these may be given in the form of lozenge, while benzoin, tolu, and copaiba are also of value. Acetic or tannic acid, given in small and frequently repeated doses, reduces the quantity of secretion.

When the combined glairy and muco-purulent condition of the expectoration and other symptoms give evidence of bronchitis of an established kind, associated with gout or abdominal torpor, a combination of calomel with antimony and guaiacum (as in Plummer's pill) is of the greatest service; but this treatment needs perseverance, discrimination, and watchfulness. The morbid surface may at the same time be medicated by the inhalation of tar, creasote, or oil of juniper, until, with the improvement of the general health, under cod-liver oil and iron, the evil is entirely removed.

E. SYMES THOMPSON.

**EXPOSURE, Effects of.**—Were the term 'exposure' to be taken in its widest significance, it might fairly claim to include a range of subjects only bounded by the limits of practical medicine. Infection naturally implies exposure to some contagious influence, poisonous gas, or malarious or other unhealthy emanation, bearing in its train a formidable sequence of ill results, and probably depending on the introduction within the system of a specific form of microbe. Many of the disorders which impair our comfort and shorten our lives may, indeed, be traced, in some degree, to exposure of some kind, to an excess of heat or of cold, to a variety of complicated reactions, arising, in whole or in part, from unnatural impressions made on the physiological processes of life by various external agencies. Any study of our subject, however, from this extended point of view, would clearly be out of place here, and effects of extreme elevation and depression of temperature will be fully considered elsewhere; so that exposure, in the sense in which it will be treated here, may be narrowed down to the results which ensue when persons of average constitutional power are submitted, for a longer or shorter time, to the influence of ordinary cold, or wet, or damp. Now, it is an old saying, that if five

or six people, of either sex, suffer shipwreck, or are wet through, or excessively chilled by moist cold, each will probably suffer in some different way. One may altogether escape, and not experience inconvenience of any kind; a second may 'catch'—as the popular expression puts it—a sore-throat, or a 'bad cold;' whilst a third may be seized with pneumonia; and a fourth with rheumatic fever.

Individual constitution or idiosyncrasy partly explains these differences, and the familiar term of a 'weak point somewhere,' if not conveying much impression of scientific accuracy, is right so far in showing that the internal congestion caused by sudden contraction of cutaneous arterioles is most naturally directed to that organ whose vessels have been weakened by previous inflammation. If the patient, therefore, have previously suffered from tonsillitis, or bronchial congestion, or rheumatism, he will be predisposed to a recurrence of the same affection on a renewal of the exciting cause. If, again, from sedentary occupation and over-indulgence in nitrogenous food, his blood be overcharged with the products of retrograde metamorphosis or of imperfect assimilation, it only needs the closure of the eliminatory agency of the skin, to provoke the irritation of internal organs, and to induce an attack of gout or rheumatism, or an acute inflammation of kidneys or liver. The effects of exposure, even in this limited sense, are thus tolerably various both in extent and in degree, and may be studied on a large scale during our greater campaigns, and in lesser degree during the ordinary autumn manœuvres, when the weather happens to be unfavourable. Here, however, everything injurious is minimised by the healthy condition of the men, their good clothing and food, and the enforced regularity of habits, which prevent, in great measure, one of the most fertile causes of damage from exposure; and among the most efficient means for preventing the potent influence of bacilli for evil, we must place all hygienic means which improve the bodily vigour. It is now well known that nothing tends so seriously to impair the power of bearing either extreme of temperature as excessive indulgence in strong drink; so that in treating anyone who has been exposed to the influence of cold and wet, we must not forget to take also into account the probable combination of the depressing effects of alcohol on the nervous system. Illustrations of this must be familiar to all, and we must all have met with numerous cases in which tramps or other persons with weakened bodily vigour have been brought into our hospitals, suffering from the effects of exposure in various degree.

**TREATMENT.**—In seeking to remedy the effects just described, it will be found that some of the cases will recover under the

influence of warmth and good food, and the generally invigorating effects of careful nursing; whilst others, on the other hand, may succumb to the rapidly destructive tendencies of acute disease, or to the slower pathological processes of chronic lung or kidney degeneration. In the treatment, therefore, of such cases, we must not only add to the genial influences of home or hospital care such special drugs as the varied development of symptoms may require, but we must carefully take into account the occurrence of various serious or profoundly disorganising complicating causes. Thus if our patient has been found in an insensible state, we may reasonably suspect cerebral hæmorrhage or alcoholic or narcotic poisoning, and act accordingly. And only when all such suspicion is finally removed can we rest on our oars, and confine our attention to the immediate effects which follow exposure of the kind indicated above. Warmth, rest, and the regulated use of stimulants and food will now be indicated, and must be employed, with all the precautions suggested by the ordinary principles of therapeutics and by common sense.

ROBERT FARQUHARSON.

**EXSANGUINE** (*ex*, without; and *sanguis*, blood).—Deprived more or less of blood—bloodless. Sometimes used synonymously with anæmic. See ANÆMIA.

**EXTRA-UTERINE FŒTATION.**  
See PREGNANCY, Diseases and Disorders of.

**EXTRAVASATION** (*extra*, without; and *vasa*, vessels).—SYNON.: Fr. *Extravasation*; Ger. *Extravasat*.

**DEFINITION.**—Extravasation is the escape of any of the fluids of the body, normal or abnormal, from the vessel, cavity, or canal that naturally contains it, and its diffusion into the surrounding tissues. The result of the effusion is also called an *extravasation*.

Extravasation, being the effect of rupture or perforation of the walls of a hollow organ, may be due to injury, to weakness of the parietal structures, to morbid conditions of the blood, or to increase of internal pressure. See PERFORATIONS AND RUPTURES.

The fluids most frequently found extravasated are blood, urine, bile, the contents of the alimentary canal, and certain constituents of morbid growths and fluid collections. The present observations will have reference only to extravasation of blood; other kinds of extravasation being described under the heads of the several organs involved.

**Extravasation of Blood.**—The blood is peculiarly liable to extravasation, the vessels being universally distributed, much exposed to injury—a very common cause of this lesion—and subject also to a constant pressure from within, which may be suddenly and greatly increased. Any portion

of the circulatory system may give way: the heart, as in fatty degeneration; the arteries, as in aneurysm; the capillaries, as in pulmonary hæmorrhage; the veins, as in the subcutaneous rupture of a varix.

When the effusion takes place into one of the serous sacs, it forms a collection of blood, variously named *hæmothorax*, *hæmatocele*, &c. If the subcutaneous, submucous, or other connective tissue, or the substance of an organ, be invaded, the effused blood finds its way between the elementary textures, separating and compressing them; and there are formed what are described simply as *extravasations* of blood, or more definitely, according to their extent, *parenchymatous* or *interstitial hæmorrhages* or *apoplexies*, *suffusions*, *ecchymoses*, *petechiæ*, or *vibices*. The extravasated blood generally coagulates; the fibrin and albuminous substances are absorbed; and the products of the decomposition of hæmoglobin, which are much more slowly removed, give rise to the familiar discolorations. The seat of effusion first appears of the colour of blood or its derivatives; but if much below the surface, the extravasation may not be visible for some days, after which time it appears of a bluish, greenish, or yellowish hue. Much less frequently the effused blood becomes encapsuled, forming a *hæmatoma* or *blood-cyst*, such as is occasionally seen in connexion with the chest or abdomen. In other cases it decomposes, and sets up gangrene around, or inflammation of the nature of severe cellulitis, which may end in ulceration. When the blood is forced between the coats of the perforated vessel, there is formed what is called a *dissecting aneurysm*. If the extravasated blood escape from the surface of the skin or mucous membranes, one form of *hæmorrhage* or a *bloody flux* is the result.

The *symptoms* of extravasation of blood are so various that they cannot be stated in general terms. If extensive and affecting vital parts, the effusion may be attended with shock, syncope, or death; and it may lead to constitutional disturbance in many forms. Local pain is not common unless the extravasation be severe. The pressure of the effused blood upon the vessels, nerves, and muscles of the part—in a limb, for example—may produce paralysis, disturbances of sensibility, œdema, loss of temperature, and even gangrene. As a rule, however, extravasations of blood are limited in size, give rise of themselves to no serious symptoms, and readily disappear by absorption.

J. MITCHELL BRUCE.

**EXTROVERSION** (*extra*, outwards; and *verso*, I turn).—The eversion or turning inside out of a part, as the eyelids or bladder. In the bladder, extroversion is associated with that condition, usually congenital, in which the anterior wall of this organ and of

the abdomen is deficient, and its posterior wall projects through the opening thus formed.

**EXUDATION** (*exudo*, I sweat).—The process by which certain of the elements of the blood pass through the walls of the blood-vessels into the surrounding tissues, as in inflammation. The term is also used to indicate the products of this process, when they are of a fibrinous or coagulable character. See INFLAMMATION.

**EXUDATION - CORPUSCLES.**—The cells found in inflammatory products, whatever their origin may be. See INFLAMMATION.

**EYE, and its Appendages, Diseases of.**—SYNON.: Fr. *Maladies des Yeux*; Ger. *Augenkrankheiten*.

It will be most convenient to arrange the consideration of the diseases of the eye according to the anatomical order of the structures affected, namely: I. Diseases of the Conjunctiva; II. Diseases of the Cornea; III. Diseases of the Sclerotic; IV. Diseases of the Iris; V. Diseases of the Crystalline Lens; VI. Glaucoma; VII. Diseases of the Optic Nerve and Retina; VIII. Diseases of the Choroid; IX. Diseases of the Vitreous Body; and, X. Diseases of the Eyelids.<sup>1</sup>

#### I. Diseases of the Conjunctiva.

1. *Inflammation.*—SYNON.: Conjunctivitis. The conjunctiva is exceedingly liable to inflammation, and its inflammations are commonly arranged in groups, which are sufficiently distinct in their typical examples, but are not separated by any definite boundary lines.

In their earlier stages inflammations of the conjunctiva possess many characters in common. They are all attended by the four signs of inflammation—heat, redness, swelling, and pain; although both the heat and the swelling are usually kept within limits by the discharge, which is often free, sometimes profuse, at first mucous, afterwards mucopurulent or truly purulent in character. If, however, the exudation be of a firmer consistence than usual, it not only produces a superficial discharge, but distends the meshes of the sub-mucous tissue, elevates the conjunctiva from the sclerotic, and causes it to overlap the corneal margin as a swollen ridge; a condition which is known as *chemosis*. The redness depends, of course, on the degree of the congestion, which may or may not be sufficient to obliterate the intervascular meshes, and to produce a uniform colour; and the pain is not severe, except in cases of very dense sub-conjunctival swelling. From other forms of inflammation, that of the conjunctiva is distinguished by certain negative characters. Unless as a result of secondary changes, or as a mechanical effect of the

<sup>1</sup> See also VISION, Disorders of; OPHTHALMOSCOPE; and OPHTHALMOSCOPE IN MEDICINE.

presence of a film of turbid secretion, the transparency of the cornea is not affected, and the acuteness of vision is not impaired. The congestion is limited to the conjunctiva, and the distended vessels can be emptied for a moment by pressure through the lower lid, so as to reveal a glimpse of the white sclerotic underneath.

In mild cases conjunctivitis is an unimportant affection, but in its more severe forms it is attended by two distinct sources of danger. During its acute stage it may produce partial or complete necrosis of the cornea, leading to great impairment of sight and not seldom to blindness; and when chronic it often occasions great hypertrophy of the papillæ of the portion of the membrane which lines the lids. These papillæ may even become converted into shaggy or warty excrescences, which mechanically irritate the corneal surface, and cause the development of vessels beneath its epithelium. In time the papillæ dwindle, and the effusion round about them contracts, thus rendering the tarsal cartilage (especially that of the upper lids) incurved, and bringing the cilia to rest upon the surface of the eyeball. Great distress and permanent impairment of vision may be thus occasioned; and the progress of the contraction may be so slow as to deprive it of any manifest connexion with the inflammation in which it had its origin.

The chief varieties of conjunctivitis are: (a) *infantile*; (b) *simple* or *catarrhal*; (c) *contagious*; and (d) *diphtheritic*.

(a) *Infantile Conjunctivitis*.—SYNON.: *Ophthalmia neonatorum*.

**ÆTIOLOGY AND SYMPTOMS.**—Infantile conjunctivitis is probably due, in most cases, to direct inoculation with vaginal secretion. It usually commences on or about the third day after birth, and passes rapidly into the purulent form. It is attended by considerable puffy swelling of the lids, and by profuse thick discharge, which soon dries upon the tarsal margins, and often causes them to cohere. If neglected or improperly treated, the disease often leads to sloughing of the cornea; but it may always be cured if it is seen while the cornea is still bright.

**TREATMENT.**—The treatment required is to wash away the discharge carefully and frequently; to apply an astringent lotion (the best is a solution of two grains of nitrate of silver to an ounce of distilled water) to the conjunctival surface every four hours, or less frequently when improvement is established; and to anoint the edges of the lids with simple ointment to prevent their agglutination. In cases of inherited syphilis mercurial inunction should be prescribed. The infant's food must be carefully regulated if it is brought up by hand; and if it is very feeble, it may take a little cod-liver oil, combined in an emulsion with two-minim doses of liquor einchonæ. Where the mother's milk fails, it

is often desirable to obtain a wet-nurse; but the local treatment is that which is chiefly important, and upon which, in most cases, entire reliance may be placed.

(b) *Simple* or *Catarrhal Conjunctivitis*.

**ÆTIOLOGY AND SYMPTOMS.**—This form of conjunctivitis is usually due to exposure to cold or to some chemical or mechanical irritant. Its most distinctive character is that the discharge is chiefly mucous, and has not much tendency to become purulent.

**TREATMENT.**—In every case the surface of the eyeball, and the lining membrane of the lids, should be carefully examined for any foreign body which may be the cause of the trouble; and if such should be found and removed, there will seldom be need for further treatment. If there is no foreign body, the two-grain solution of nitrate of silver, or of sulphate of zinc, may be placed within the conjunctival sac, by means of a quill or dropping-bottle, every two or three hours, and speedy recovery will usually be the result. In cases of very mild type, one or two applications of the astringent may be sufficient; and these may be supplemented by the use, in the same manner, of a solution of cocaine with boric acid. A good formula for this purpose contains two grains of cocaine hydrochlorate, and four of boric acid, to the ounce of distilled water. During the treatment the eyes should have functional rest, and should be sheltered from external cold, from dust, and from glare.

(c) *Contagious Conjunctivitis*.—SYNON.: *Purulent Ophthalmia*.

**ÆTIOLOGY AND SYMPTOMS.**—In this form the discharge rapidly assumes a purulent character. This may happen when the simple form is aggravated by the state of the patient or by accidental circumstances; or when the disease is produced by inoculation with the discharge from a similar case, or with contagious pus from the urethral or vaginal mucous membrane. The state of the patient which is most likely to promote the development of the contagious form is that in which the conjunctiva is beset with the granular semi-transparent bodies, formed by aggregations of lymph-corpuscles, which are known as 'sago-grains' or follicular granulations. These bodies are commonly present in the eyelids of persons (especially of young persons) who are crowded together under insanitary conditions of living, as in barracks, camps, or badly regulated schools; and their presence renders the conjunctivitis of simple irritation prone to assume a purulent character. It is impossible to say how soon the discharge of conjunctivitis becomes contagious; or capable of reproducing the disease in others; but its activity in this respect seems to bear some proportion to the intensity of the inflammation which produces it; and the activity of gonorrhœal pus is probably greater than that of any conjunctival product. In the

more intense forms of purulent ophthalmia there is great swelling of the lids and of the ocular conjunctiva, early chemosis, and a tendency to speedy sloughing of the cornea; while the milder forms pass into the catarrhal by imperceptible gradations.

**TREATMENT.**—In the space available for the purpose in these pages, the treatment of contagious conjunctivitis cannot be described in detail. It mainly rests upon the action of local astringents, graduated in strength according to the severity and the stage of the disease. In the worst cases the eyelids must be everted, and the whole of the palpebral conjunctiva carefully touched with a stick composed of one part of nitrate of silver fused with four parts of nitrate of potash. The caustic should be neutralised by a drop or two of a solution of common salt, applied by means of a camel's-hair pencil, before the lid is suffered to return into contact with the cornea; and the cauterisation must be done carefully and with a light hand, so that the resulting eschar may include only the epithelium; for if the basement membrane is destroyed, there will be danger of subsequent adhesions between the eyelids and eyeball. The cauterisation should be repeated about every eight hours, or as soon as the eschar falls, and in the intervals, if the patient is awake, the conjunctiva should be gently sprayed or syringed every hour with a weak antiseptic lotion at a comfortable temperature. Diluted Condy's fluid, solution (1 in 5,000) of mercuric perchloride, or (15 per cent.) of Barff's boroglyceride, are all suitable for this purpose. The tension of chemosis may be diminished by radial incisions, outwards from the corneal margin, carried nearly down to the sclerotic. The strength must be supported by good diet and tonics; and the nervous system calmed by anodynes. In milder cases the principle of treatment must be the same, but the local applications less severe; and in chronic cases the local applications must be continued, after apparent recovery, so long as any residual thickening, capable of undergoing eventual contraction, can be found lurking in the palpebral folds.

(d) *Diphtheritic Conjunctivitis.*—This malady has chiefly been made known to us by the observations of German writers, and very few authentic instances have been recorded in this country. But it has from time to time prevailed extensively in Berlin, and might at any time make its appearance amongst ourselves. The writer has seen one remarkable instance in which the disease occurred with great severity in a child, whose eyes were bathed with milk as a domestic remedy for what seems to have been a mild ordinary conjunctivitis; and the coincidence seems to have a special interest in relation to recent researches into the aetiology of diphtheria.

**SYMPTOMS.**—Diphtheritic conjunctivitis is

attended with great heat and pain, and with very hard, brawny swelling of the eyelids; but its most characteristic symptom is the infiltration of the sub-conjunctival tissue by the so-called diphtheritic effusion, which does not form a pellicle upon the surface, but distends and fills the cavities of the areolar tissue. The result is to produce a pale, firm swelling of the conjunctiva, and a great tendency to rapid sloughing of the cornea. The subjects of the malady are mostly feeble and badly fed children, and the cases are described as being almost hopeless unless early admitted into hospital.

**TREATMENT.**—The indications for treatment are chiefly to support the strength by suitable regimen; to apply ice or bags of freezing mixture to the lids during the hot stage; and to change the cold applications for hot ones as soon as the period of resolution, absorption, or repair can be said to have commenced. In the meantime iron and quinine should generally be administered internally.

*Pemphigus of the Conjunctiva.*—A very formidable, but fortunately rare, variety of conjunctival disease appears to be a kind of pemphigus. See PEMPHIGUS.

**ÆTIOLOGY AND SYMPTOMS.**—In its early stage pemphigus of the conjunctiva displays itself by the formation of bullæ, which are of small size and inconspicuous, and are seldom followed by the raw surfaces commonly left elsewhere. This stage seldom excites much attention, and it is followed by a slow process of conjunctival atrophy, which, in time, leads on to disturbance of the corneal epithelium, and ultimately to complete opacity. The conjunctival atrophy gradually obliterates the folds of the membrane, and renders the lids immovable upon the globe, frequently causing also inversion of cilia, which add to the pre-existing irritation.

**TREATMENT.**—The only hope of dealing successfully with conjunctival pemphigus appears to depend upon the early recognition and constitutional treatment of the general malady; for which purpose the chief reliance must be placed upon the preparations of arsenic, in combination with tonics and anodynes. When the period of atrophy has commenced, it is seldom, if ever, arrested. The apparent adhesions between the lids and the globe often suggest operative measures, but these are not recorded ever to have been successful. In one case, the writer dissected off the whole of the affected conjunctiva of the globe, and replaced it by transplanting that of a rabbit. The graft united well, and, for a time, the disease appeared to be arrested. In a few weeks, however, or as soon as the graft had become completely dependent upon the nutritive processes of the patient, the new structure became affected by atrophy, and the malady pursued its usual destructive course.

2. *Episcleritis*.—An affection which is apparently but not really conjunctival, being situated in the tissue between the conjunctiva and the sclerotic, is that which has received the name of *episcleritis*, and which was formerly described as 'scleritis with inflammation of the insertion of a rectus muscle.'

**SYMPTOMS.**—It appears as an elevated patch of congestion, gradually passing into the natural level and appearance of the parts, and seated on the ocular surface near the corneal margin, most frequently on the temporal side. On close examination, the congestion, with the exception of a few dilated vessels, is seen to be sub-conjunctival, and to be attendant upon a circumscribed but not sharply defined swelling or thickening, which is adherent to the sclerotic, and which presents, in the interstices between the blood-vessels, an appearance as if it consisted of some new deposit, generally of a yellowish tint, external to that membrane. The swelling is indolent, chronic, and in itself generally painless, although it is sometimes accompanied by severe neuralgia. The subjects are most frequently women, especially such as are anæmic or otherwise out of condition. *Episcleritis* may last for months with little change, and it seems to be harmless as regards the other structures of the eye.

**TREATMENT.**—The writer has found *episcleritis* resist all medication except the internal administration of mercury, to which it will often yield in the course of a short time. The best preparation is the perchloride, in doses not exceeding  $\frac{1}{16}$  of a grain, which may usually be combined with five or ten minims of the tincture of perchloride of iron, and often with quinine. At the same time it is often desirable to sprinkle a little dry calomel over the swelling once in twenty-four hours; but this application is less important than the internal treatment, and should not be continued unless it is soon and distinctly beneficial. When the congestion of the patch is considerable, the action of other remedies will often be promoted by the occasional application of a leech to the temple of the affected side.

3. *Hæmorrhage*.—Effusion of blood beneath the conjunctiva may occur spontaneously, but is generally traceable either to a direct injury or to violent exertion. Thus it may follow slight blows upon the eyeball, as from a twig or switch; or may be produced by a paroxysm of coughing, especially in pertussis; or may occur from the rupture of a vessel during parturition, or upon lifting a heavy weight. It is always unsightly. When traceable to any of the foregoing causes, the hæmorrhage is usually a matter of no moment; but when it happens during the night in young people, it should lead to a suspicion of nocturnal epilepsy, which has often been first discovered by its means. Moreover, in advanced life, more especially when occur-

ring without adequate cause, it may point to arterial brittleness, of a kind which may indicate danger of a like hæmorrhage within the cranium. On these grounds it is a symptom which always calls for full inquiry into its causes, and which may sometimes afford useful warning of impending danger.

**TREATMENT.**—Absorption may be promoted by covering the closed lids by a compress moistened with a lotion of spirit and water, or of tincture of arnica and water if an appearance of more decided medication is desired.

II. **Diseases of the Cornea.**—Diseases of the cornea, as already indicated, are often secondary to those of the conjunctiva, and may arise in their course as complications.

### 1. *Ulceration*.

**ÆTIOLOGY AND SYMPTOMS.**—To the present group belong all the corneal ulcerations of purulent ophthalmia, whether infantile or of a later period of life; and also the forms of corneal ulcer which are produced by the friction of eyelids rendered rough by inflammation, or by the friction of eyelashes which have been turned inwards by distortion of the tarsal cartilage. When ulceration of the cornea occurs in the course of conjunctivitis, it at once invests the latter malady with a highly formidable character. The corneal tissue, once destroyed by ulceration, is not reproduced in its original transparency, but only as a more or less dense and opaque white cicatrix, which is at the same time disfiguring to the appearance and an impediment to vision. If the ulcer should perforate, the iris almost necessarily becomes adherent to the cicatrix; and if the loss of substance is of large superficial extent, the resulting cicatrix is often thin and feeble, so that it is rendered prominent by the pressure within the eye, producing the condition which has been called 'staphyloma,' and gradually elevating and distorting the surrounding portions of clear cornea. The first effect of the healing of a corneal ulcer is generally to flatten the natural curvature of the membrane; but the secondary effect, if the cicatrix becomes prominent, may be to modify this curvature in various ways. Hence it follows, even when a cicatrix of the cornea is surrounded by a still transparent annulus, behind which an artificial pupil may easily be made by the excision of a portion of the iris, that the surgeon cannot predict with any certainty the quality of the vision which will be obtained, unless he is able, before operating, to determine the state of the corneal curvature. This is only possible when the margin of the pupil is so far free that it can be dilated with atropine sufficiently to render the fundus of the eye visible with the ophthalmoscope. When this can be done, any portion of cornea through which a clear view of the retinal vessels can be obtained by the surgeon

will also afford clear vision of external objects to the patient; but, if no such place can be discovered, a very cautious opinion should be given with regard to the degree of benefit which may be hoped for from an operation.

**TREATMENT.**—The extreme importance of the cornea to the visual function renders it necessary that its integrity should be guarded with the greatest possible care. In any case of conjunctivitis, of even moderate severity, the cornea should be watched from day to day, and any appearance of turbidity about its central portion, or of elevation or irregularity of the epithelium at its margin, should lead to a reconsideration of the treatment which is being pursued. The former of these conditions is the ordinary precursor of sloughing ulcer or necrosis; the latter, of the extension to the cornea of an inflammatory process.

The general principles which govern the treatment of sloughing ulcer are, that the eye should be kept under the influence of eserine, which has a marked effect in checking the extension of ulceration by arresting the migration of white corpuscles; that any astringents which may be applied to the conjunctiva should be prevented from coming into contact with the cornea; that strength should be supported, pain relieved, and local nutrition stimulated by hot applications. When the ulcer continues to spread, its progress may often be arrested by diminishing the tension of the globe by the evacuation of the aqueous humour; and this may be accomplished either by repeated paracentesis at the corneal margin, or by Saemisch's method of cutting through the base of the ulcer, and reopening the incision daily until a process of repair is well established, or by the performance of iridectomy. Of these three courses, the last-named is the most generally applicable. It not only produces the immediate effect which is desired, but it has also the incidental advantage of establishing an artificial pupil at the side of the cicatrix.

The application of eserine is best effected by using a solution of the neutral sulphate, of the strength of four grains to the ounce of distilled water; and a drop of this solution may be placed within the conjunctival sac twice or thrice daily.

The sloughing ulcers of the cornea which arise from causes other than conjunctivitis, as injury, or failure of nutrition, must be treated upon the principles which have already been laid down. There are, however, inflammatory ulcers which require the use of local applications of a stimulating kind, among which dry calomel and other mercurials hold a prominent place. Such ulcers have usually a leash of vessels running from the corneal margin, and are often obstinately recurrent; whence they are known as 'recurrent vascular ulcers.' They are usually connected with some manifest systemic de-

range, and are often attended by photophobia. They leave scars upon the cornea, of a size and opacity proportionate to their extent and depth; and on this account it is desirable, whatever constitutional treatment may be required, to heal the ulcers themselves as speedily as possible, by the aid of local applications. In the early stages of the ulceration, eserine should be used; but afterwards either dry calomel or an ointment containing from ten to thirty grains to the ounce of the precipitated yellow oxide of mercury. This ointment was introduced into practice by the late Dr. Pagenstecher, of Wiesbaden, and is often called by his name. In very obstinate cases the late Mr. Critchett recommended setons in the temporal regions; but the operation of iridectomy will often afford a still more efficacious remedy. Where there is much photophobia, the use of eserine is especially indicated, because, in addition to its action above mentioned, it produces contraction of the pupil, and thus gives comfort by lessening the quantity of light which is admitted into the eye. If the photophobia is very severe or intractable, it is often beneficial to divide the orbicularis muscle freely at the outer canthus, so as to diminish the pressure which is caused by its spasmodic contraction, and which sometimes seems to be a chief cause of the irritability. After such an incision, a cold compress should be applied, and the patient kept in the dark for a few hours, when there will often be a marked alleviation of this distressing symptom, and a greatly increased general amenability to treatment.

**2. Inflammation.**—**SYNON.**: Keratitis.—Inflammation of the cornea presents three distinct types, the *suppurative*, the *vascular*, and the *interstitial*.

(a) *Suppurative Keratitis.*—Suppurative inflammation or abscess of the cornea seems to be essentially a phlegmon or boil of the corneal tissue, a portion of which dies, and is cast off in the form of a slough.

**SYMPTOMS.**—The abscess commences as a very tender grey spot in the cornea, surrounded by a zone of turbidity, and accompanied by a good deal of ciliary neuralgia, as well as by a variable degree of lachrymation, conjunctival congestion, and intolerance of light. Under the influence of atropine, hot fomentations, and such constitutional treatment as the state of the patient may demand, the threatened suppuration is sometimes averted, and the turbidity clears away. More commonly pus is formed, and makes its way either externally, leaving an ordinary ulcer; or internally, producing the condition called *hypopyon*, in which there is pus in the anterior chamber. Sometimes it separates the corneal laminae, by gravitation, to a considerable extent before perforating them, and is then called *onyx*, from a resemblance to the lunula at the base of a finger-nail.

**TREATMENT.**—When suppuration is no longer doubtful, the best practice is to evacuate the abscess by a puncture from within, by thrusting a cutting needle into the anterior chamber near the corneal margin, and then causing its point to penetrate the cavity of the abscess. The mingled pus and aqueous humour will escape as the needle is withdrawn, and its wound of entrance may be reopened once or twice daily by a probe, so as to insure the complete removal of all inflammatory products, until the healing process has made some way. If the abscess has burst internally before the case is seen, atropine should be applied without delay. If the pupil dilates fully, and the quantity of pus in the anterior chamber is but small, the case may be left to the *vis medicatrix natura*, care being taken to enforce rest and to exclude noxious influences. If the quantity of pus is large, it should be let out by paracentesis; and if the atropine reveals adhesions of the iris, iridectomy should at once be performed. An abscess which has burst externally leaves simply an ulcer, generally with a disposition to heal readily, and requiring only such treatment as has already been described.

(b) *Vascular Keratitis.*—Vascular inflammation of the cornea is often a very severe and protracted malady, which usually leaves behind permanent opacity and impairment of sight.

**SYMPTOMS.**—It commences, in typical cases, by the formation of two crescent-shaped patches of vascularity, one at the upper and the other at the lower portion of the cornea. The patches are formed by the development on the corneal surface of innumerable fine blood-vessels, so closely packed together that the interstices which separate them are scarcely discernible by the naked eye, and the affected parts present a uniform aspect of vivid redness. The crescents are somewhat elevated above the general corneal surface, and each crescent is bordered, along its concave or advancing edge, by a line of precursory epithelial turbidity. At the same time that the crescents increase in size, the borders of precursory turbidity are pushed before them; until at first these, and afterwards the crescents themselves, may meet and coalesce on the horizontal diameter of the cornea, so that its whole surface may become uniformly red. When this stage is reached, vision is almost abolished, but there may still be much intolerance of light. The corneal tissue is softened, and its margin is surrounded by a zone of sclerotic vascularity, which is visible through the congestion of the conjunctiva. As the inflammation subsides, the vascular crescents slowly recede from the centre of the cornea towards its circumference, and finally disappear, leaving behind them a dense opacity of an extremely obstinate

character. A severe case of vascular keratitis generally affects both eyes, and threatens a long period of actual blindness, followed by a long period of very imperfect vision. The worst examples of the malady are those which have been treated at the outset by astringent or irritating applications; and, even in the slighter forms, the malady is nearly always obstinate and protracted. As long, however, as the march of the vascular crescents, or their precursory turbidity, has not encroached upon the portion of cornea in front of the pupil, so long vision is not seriously jeopardised.

**TREATMENT.**—The great object of treatment is to arrest the new vascular development at a comparatively early stage; and for this purpose it is necessary to have recourse to eserine and sedatives locally, and to such constitutional treatment as the general condition may require. A solution of two grains of the neutral sulphate of eserine, with from two to four grains of hydrochlorate of cocaine, in an ounce of distilled water, should be dropped into the eye twice daily, and the closed lids should be frequently fomented with hot poppy decoction, or with cold solution of extract of opium in water, according as one or the other temperature is the more agreeable to the feelings of the patient. Apart from any special indication, the medicines most generally useful are those which appear to influence local nutrition through the central nervous system, such as the iodide and bromide of potassium, and the sulphate of quinine. These, if they are likely to exert a beneficial effect, generally do so speedily; and if the malady should be rapidly extending, it is always prudent to reconsider the prescription without much loss of time. In severe cases, especially when the lids are somewhat tumid and there is much photophobia, a leech may often be applied with advantage, usually over the temporal muscle, close to the outer margin of the orbit, or a little blood may be taken more rapidly, by means of Heurteloup's artificial leech; and when, notwithstanding treatment, the malady pursues its course unchecked, a large iridectomy should be made without undue delay. The operation not only tends to arrest the vascular formation, but it also leaves a lateral pupil through which good sight may often be obtained long before the transparency of the central parts of the cornea is restored. In some cases, the writer has seen excellent results from peritomy; that is, from excising the annulus of conjunctival and subconjunctival tissue which immediately surrounds the cornea. The strip excised should be about 3 mm. in width; and the excision may sometimes be limited to the bases of the vascular crescents.

*Development of vessels upon the cornea.*—It is necessary carefully to distinguish vascular keratitis, properly so called, from that

development of vessels upon the cornea which may occur in connexion with the cicatrisation of ulcers, or in consequence of the friction of lids left granular by conjunctivitis. In both these forms the new vessels are arborescent and irregular in their distribution, instead of being closely packed together; and they are not attended by the pink zone of circum-corneal congestion, which is never absent in true corneal inflammation.

The vessels which attend the formation of cicatrices generally dwindle in course of time; while those produced by granular lids, and which, when they are very abundant and closely set, constitute the condition called *pannus*, will often disappear without direct treatment if the state of the lids themselves can be favourably modified by the application of astringents or by other means. When residual granulations are large and numerous, they may be treated by crushing them with forceps, by scraping, or by electrolysis; for which purpose they should be separately punctured by a platinum needle, connected with the negative pole of a galvanic battery. A weak current only is required, and it may be suffered to pass through each granulation for from ten to twenty seconds. In many cases the vascular network of *pannus* will be comparatively absent from the lower third of the cornea, so that sight may be much improved by an artificial pupil made in a downward direction. When *pannus* covers the whole cornea with a close vascular network, so that sight is almost destroyed, and when it resists milder treatment, it may sometimes be cured by inoculation with the discharge of infantile purulent ophthalmia. The pus is inserted between the lids, and the artificial malady suffered to run its course unchecked, except by cleanliness and frequent bathing. When the discharge has ceased, the cornea will often clear in a surprising manner, and its abnormally vascular state protects it, to a very great degree, against the risk of sloughing. Still, this risk is by no means absent, and the treatment by inoculation should be regarded only as a last resource. A somewhat similar effect may be obtained by the inflammation which is excited by bathing the eyes with an infusion of the seeds of jequirity; but this method is scarcely less dangerous than that by inoculation.

(c) *Interstitial Keratitis*.—This is a chronic malady which is seen chiefly, or perhaps exclusively, in the subjects of inherited syphilis, who possess the peculiar teeth and *facies* which Mr. Hutchinson has shown to be characteristic of their inheritance. The disease was long described as a variety of 'strumous ophthalmia;' and, although the late Sir William Wilde pointed out how frequently it was associated with deafness, and also laid stress upon the value of perchloride of mercury in its treatment, its

syphilitic character seems to have been first suspected by Mr. Hutchinson, who, having once obtained the clue, followed it with characteristic diligence until he arrived at a conclusive demonstration of the accuracy of his suspicion.

**SYMPTOMS.**—Interstitial keratitis commences as a slight cloudiness of the central portion of the cornea, with some roughening or irregularity of the epithelium. It extends from the centre towards the margin, and is liable to be attended, in different cases and at different stages of its course, by variable degrees of ciliary and corneal congestion, and intolerance of light. If neglected, or if treated by irritants, it is liable to assume the characters of vascular keratitis, and also to extend to the iris, in such instances often doing irreparable mischief. It is most common during childhood, but its appearance may be delayed until adolescence, or even until adult age; and, in such cases, usually appears to be determined by some general or local exciting cause, such as bodily illness, or direct injury. It attacks both eyes, one commonly somewhat later than the other, and its course is often protracted over several months. When severe, it leaves some residual cloudiness of the cornea, and, even when mild, it is doubtful whether the cornea ever entirely regains the transparency of health. Still, when a case is seen and judiciously treated early, the prognosis may generally be a favourable one.

**TREATMENT.**—The treatment consists primarily in the avoidance of all irritants; the use of eserine and local sedatives, especially cocaine; and the administration of perchloride of mercury, or of iodide of potassium, with or without iron or cod-liver oil. When they are not contra-indicated by any special circumstances, the perchloride of mercury and the oil are the remedies on which the greatest reliance may be placed. The earliest indications of photophobia, showing, as they do, that light is acting as an irritant, should be met by confinement to an almost darkened room, and by frequent bathing of the closed lids with cold water; but in fine weather daily exercise should be taken in the open air, the eyes being covered for the time with a black silk bandage and compresses of carded wool, so as to exclude light entirely. As soon as photophobia subsides, these precautions may be left aside—the eserine and mercury being still continued, at least until the acute stage of the malady has entirely passed away. After this the absorption of residual opacity may be promoted by the application, once daily, of a morsel of an ointment containing a small quantity (about ten grains to an ounce) of the precipitated yellow oxide of mercury.

In cases which have been neglected, or aggravated by irritants in their early stages, and in which the phenomena of ordinary

vascular keratitis become grafted upon the interstitial, it is generally desirable to perform iridectomy with as little delay as possible.

3. *Arcus Senilis*.—The condition thus named (although the adjective is not always appropriate) is fully described elsewhere (see *ARCUS SENILIS*). It may be distinguished from the peripheral zones of opacity, which are sometimes left after the subsidence of certain forms of keratitis, by the circumstance that arcus never extends quite to the margin of the cornea, but is always surrounded by an annulus of transparent tissue.

Besides the foregoing, there are a few other forms of corneal disease, of comparatively rare occurrence, which it would be beyond the limits of these pages to describe, but which must be treated on the same general principles; and there is also the malformation known as 'conical cornea,' which falls wholly within the domain of surgery.

III. *Diseases of the Sclerotic*.—Diseases of the sclerotic, which were once regarded as a numerous and important group, have been reduced by recent investigations to comparatively insignificant proportions.

*Inflammation*.—*SYNON.*: Scleritis. — Excepting in a narrow annulus immediately around the cornea, the sclerotic is almost extra-vascular; and any real inflammation of its structure is almost confined to this particular region, where it seldom occurs excepting as a complication or as a part of some of the more severe forms of iritis or keratitis, especially when either of these affections extends to the ciliary body. In such cases we often see the sclerotic undergo inflammatory softening, as a result of which the ciliary region may be much altered in shape, yielding to the distension of the eyeball and to the traction of the recti muscles, and becoming distinctly elongated. Occasionally the sclerotic may be so much softened and thinned as to bulge into irregular prominences around the cornea, generally under the upper lid; and this condition is described as *sclerotic staphyloma*.

*TREATMENT*.—The inflammations thus arising call for no other treatment than that which is demanded by the more important inflammations of the cornea, the iris, or the ciliary body, with which they are associated; except that any evidence of yielding of the sclerotic would be a reason in itself for the performance of iridectomy, in order to preserve the shape of the eyeball by diminishing its tension. It was once believed that the sclerotic, in its character of a fibrous membrane, was especially prone to gouty or rheumatic inflammation; and it is perhaps true, though certainly not proven, that the tendency of iritis or of keratitis to spread to the anterior sclerotic zone is more marked in persons of gouty or rheumatic diathesis than in others. The possibility is at any rate sufficient to require, in all these cases, an in-

vestigation of the tendency to lithic acid formation, and the use of appropriate remedies when this tendency is discovered. But a large proportion of the examples of supposed gouty or rheumatic ophthalmia are nothing more than cases of the sub-acute or remittent form of glaucoma; and the pain associated with them is not really rheumatic but simply tensive. Vision has been irremediably lost, in hundreds of instances, because a belief in the rheumatic character of these affections has interfered with the timely performance of iridectomy; and the proposal to adopt the epithet 'rheumatic,' in any form of eye-disease, is one which should be scrutinised very closely before it is accepted as a guide to practice.

IV. *Diseases of the Iris*.—In so far as they come into the province of the physician, diseases of the iris are not numerous, and are almost limited to the varieties of inflammation of that membrane.

1. *Inflammation*.—*SYNON.*: Iritis.—Iritis may be classified, according to its actual or supposed causes, as rheumatic or syphilitic; or according to the nature of the morbid process, as *plastic*, *serous*, or *suppurative*. The former classification must often rest upon very slender grounds, and the latter has the great advantage of expressing facts rather than inferences.

(a) *Plastic Iritis*.—*SYMPTOMS*.—In plastic iritis the first symptom is usually some loss of the natural lustre of the surface of the iris, and of the clear definition of its fibres, together with some damping or alteration of its colour. These changes are probably always due to turbidity of the aqueous humour, and they may be imitated more or less closely by turbidity of the cornea, and especially by disturbance of its epithelium. In iritis, however, they are associated with a diminished range and quickness of pupillary variation under variations of light; and, in a short time, with the effusion of plastic lymph, by which the margin of the pupil becomes tied down, here and there, to the surface of the anterior capsule of the crystalline lens. At the same time there is usually some congestion of the conjunctiva, and of the zone of fine vessels immediately around the cornea in the sclerotic. There is frequently more or less pain, especially towards night, but this is a very uncertain symptom. In severe cases, and especially in such as are clearly syphilitic in their character, the quantity of effused lymph may be very considerable, so as quite to cover the pupil, while in mild cases it is only sufficient to fasten down the margin here and there. Iritis is sometimes a very insidious and seemingly slight affection, the real gravity and importance of which may be wholly overlooked by the patient.

*TREATMENT*.—The first principle of treatment is to prevent the formation of adhe-

sions, or to break them if they have been formed; and for this purpose our main reliance must be placed upon the instillation of atropine. The anatomical structure of the eye is such that a moderately contracted pupil is in contact with the lens-surface, while a fully dilated pupil is separated from it by a film of aqueous humour. Hence, as long as the pupil is contracted, any lymph which is effused tends to the immediate formation of adhesions; while, as soon as the pupil is dilated, the lymph diffuses itself harmlessly in the surrounding fluid, and no adhesions are produced. In ordinary circumstances, and in cases of only ordinary severity, the iritis then runs its course without inflicting any permanent injury, and vision is completely restored as soon as resolution has taken place. When, on the contrary, the pupil cannot be dilated, the lymph deposited in the area of the pupil forms an impediment to vision; and the adhesions themselves tend to render the iritis a recurrent affection, which is apt to return again and again until the eye is disorganised and destroyed.

The first principle of treatment is, therefore, to produce and maintain dilatation of the pupil; and for this purpose it is necessary to use some active mydriatic. The neutral sulphate of atropine is usually the most convenient agent for the purpose, and it should be used in a solution containing four grains to the ounce of distilled water. The pharmacopœial solution of atropine, which contains spirit, should be avoided on account of its irritating action. Of the pure watery solution, a drop should be carefully placed within the lids by a dropping-tube or quill, repeated in five minutes, and again in another five minutes, and this threefold application should be repeated three times a day. A mydriatic agent still more powerful and more rapid in its action than atropine has lately been introduced into practice in *duboisine*, the active principle of an Australian shrub, *Duboisia myoporoides*. Duboisine should be used in a watery solution, of the strength of four grains to the ounce; and it is said to have less tendency than atropine to produce local irritation. The hydrochlorate of cocaine may be combined in solution with either of the foregoing, and will not only assist their mydriatic action, but will also greatly promote the comfort of the patient. If the pupil can be fully dilated in twenty-four hours, no other treatment will be necessary than to maintain the dilatation by using the mydriatic less frequently, and to protect the eye from being injured by exertion, or by exposure to great variations of temperature or of light. If, on the contrary, after the use of atropine or duboisine for twenty-four hours, the pupil either remains contracted or dilates irregularly, showing that it is bound down here and there, it is necessary to have recourse to mercury without further delay, and

to use one of the preparations, such as blue pill or calomel, with which the effect of the medicine upon the system can be rapidly secured. There is never any occasion to carry the effect of the mercury farther than to the formation of a slight line upon the gums; and, in most cases, as soon as this line is perceptible, a notable amelioration of the eye-symptoms will be observed. It is desirable, however, that this degree of mercurial influence should be reached quickly, in order to cut short the disease as soon as possible; and when it has been reached, it will usually require to be maintained, for some days at least, by the administration of smaller and less frequent doses. In favourable cases, under the combined influence of mydriatics and mercury, the effused lymph will be absorbed, the adhesions broken through, and the eye restored to its original condition. In those of a less favourable character, the inflammation will, indeed, subside; but the adhesions will remain, and the pupil will be left permanently more or less crippled and distorted. Whether or not sight will be impaired will chiefly depend upon whether the effused lymph has formed a film or membrane across the pupillary opening. In the worst cases, notwithstanding treatment, the inflammation may extend to the ciliary body and choroid, and may produce functional destruction of the eye. This scarcely happens except when the iritis has been of great original severity, and when it has been neglected, or aggravated by irritants, in its early stages. Even the suspicion of iritis should absolutely preclude the use of the astringent applications on which we have mainly to rely in the treatment of the inflammations of the conjunctiva.

If an iritis is not seen until it has been three or four days in existence, so that the adhesions have had time to acquire a certain degree of firmness, it is not desirable to wait twenty-four hours before having recourse to mercury. The mineral should be given without further delay, so that it may be abandoned if atropine should dilate the pupil, and may be pushed if dilatation cannot be produced.

While the atropine, or atropine and mercury, are being employed, the remainder of the treatment must be governed by general considerations. Rest of the other eye must be strictly enforced; local depletion may be practised whenever the congestion is considerable in degree; and such a regimen and mode of life must be prescribed as the patient can bear. Unless there is photophobia, it is seldom or never necessary to exclude light altogether from the eye; and, when photophobia is present, it is better to apply a protective bandage than to keep the patient in a dark room. The latter practically excludes him from cheerful companionship, and leaves him to dwell upon his troubles in darkness and

solitude. Pain, if present notwithstanding the use of cocaine, should always be subdued, either by combining a sufficient dose of opium with the mercury, or by the subcutaneous injection of a solution of morphine. However the anodyne is administered, provision should be made for repeating it sufficiently often to produce and maintain the desired effect.

When recovery takes place leaving adhesions, these will, in the majority of cases, lead to a second attack of iritis, and this is almost always the predecessor of regular recurrence. In a few cases, however, the second attack does not follow; but, whenever it occurs, the tendency to future mischief should be stopped by surgical means, either by the detachment of the adhesions or by the performance of iridectomy.

(b) *Aplastic Iritis*.—The aplastic form of iritis differs from the plastic in the greater quantity and the more liquid condition of the effusion, which does not form adhesions, but distends the eyeball and compresses its contained structures. In a well-marked case the pupil is contracted and insensible to atropine (which in all probability is not absorbed); the aqueous humour is turbid; the iris is pushed back and its anterior surface appears concave; vision is greatly impaired; and the eyeball is perceptibly hardened to the touch.

TREATMENT.—Until the distension is relieved, no remedies will be effectual; and, when it is relieved, they generally cease to be needed. The treatment should be either by frequently repeated paracentesis of the anterior chamber or by a large iridectomy or sclerotomy, and the latter is generally to be preferred. Aplastic iritis occurs chiefly in persons of unhealthy or broken-down constitution; which may perhaps account for the unorganisable character of its products. As soon as the distension of the eyeball is relieved, the pupil is readily dilated, and the iritis soon subsides.

(c) *Suppurative Iritis*.—In a small number of cases iritis assumes from the first a suppurative character, and leads to the formation of pus in the anterior chamber.

TREATMENT.—Such a condition calls for atropine; for stimulating and tonic medicines rather than for mercury; and for the evacuation of the pus by paracentesis if it is considerable in quantity, or if its presence appears to be a source of increased irritation.

(d) *Serous Iritis*.—This term, which would perhaps be more appropriately used for the aplastic form of iritis, has been applied by continental writers to a form of disease which was described in old books as 'aquo-capsulitis,' and in which the posterior surface of the cornea participates with the iris in the inflammation.

ÆTIOLOGY AND SYMPTOMS.—Serous iritis usually first attracts attention by occasioning a slight dimness of vision. There will often

be no congestion, or scarcely any, but the movements of the pupil will be sluggish, and careful examination will discover one or more fine points of adhesion to the anterior capsule. But the most characteristic appearance of the disease is situate upon the lining membrane of the cornea, which will be found covered by a number of minute circular dots, ranged in a pyramidal outline. The base of the pyramid corresponds with the lower corneal margin; the apex encroaches more or less upon the pupillary region. As the disease progresses, the dotted pyramid increases in density and conspicuousness, and the pupillary adhesions increase in number and extent. The malady usually runs a very chronic course, and often leaves some permanent diminution of vision. In a certain proportion of cases it seems to be independent of any known cause; in others it follows some constitutional affection (the writer has seen a very severe case, in a young lady, consecutive to mumps); in others it is associated with constitutional syphilis. After injury to an eye, serous iritis sometimes appears in the other as the first stage of sympathetic ophthalmia.

TREATMENT.—This will include, in the first place, careful consideration of the state of the general health, and endeavours to correct whatever may be amiss. The eyes should be kept at rest, the pupils dilated but protected from bright light, and mercuric chloride, or iodide of potassium, or both, may be given in suitable doses, the efficacy of these remedies being manifest in the non-syphilitic as well as in the syphilitic subjects of the disease. Where the adhesions are numerous, iridectomy may be required to relieve dragging. The cases are usually chronic, and many months may elapse before the eyes are restored to usefulness.

2. *Inflammation of the ciliary body and choroid*.—SYNON.: Cyclitis; Irido-choroiditis. In some instances, which fortunately are not numerous, iritis is not confined to the membrane in which it originates, but spreads backwards to the ciliary body and the choroid. The most marked examples are those in which the original inflammation has been excited by morbid changes, resulting sometimes from disease, but more frequently from injury, in the opposite eye; and these cases are called *sympathetic ophthalmia*. They have been generally supposed to depend upon the propagation of peripheral irritation through a nervous centre, and to point very clearly to the presence of some central nerve-irritation, or functional failure, as the essential point of difference between the iritis which dies out as a localised affection, and that which spreads by continuity to the deeper parts of the eye. Recent observers have endeavoured to connect the phenomena with the presence and the migrations of microbes. However occasioned, the

issue of declared irido-cyclitis or irido-choroiditis is generally disastrous; for the inflammation is always of a plastic character, and the effused lymph is scarcely ever absorbed in time, or with sufficient completeness, to prevent its contraction from inflicting profound injury upon the visual apparatus. The perceptive layer of the retina is not only in contact with the choroid, but the rods and cones derive the materials of their nutrition from the chorio-capillaris; and hence, as regards these delicate structures, an inflammation of the choroid, upon which they are directly dependent, is of far greater importance than an inflammation of the retina itself, which may be limited to the connective tissue of the fibre layer, and may leave the precipient elements almost unaffected.

**SYMPTOMS.**—The first sign of the extension backwards of iritis is usually furnished by tenderness of the ciliary zone, so that this region feels acutely the slightest touch of a probe, or of the end of a rolled paper spill, which is a more delicate instrument for testing the sensibility of the ocular surface. At the same time there is always a greater degree of impairment of vision than the iritis alone will explain, together with increased general congestion of the eye, and, in many cases, with an appearance of visible vessels on the iris.

**TREATMENT.**—The treatment to be pursued does not differ materially from that which is required by the more severe forms of simple iritis; and consists of depletion from the temple, generally by means of Heurteloup's leech; the application of atropine; the administration of mercury, both internally and by inunction upon the brow; the control of pain; and the maintenance of strength. In sympathetic cases, the eye in which the mischief originated should be removed, even although the usefulness of this proceeding is somewhat doubtful when once the secondary affection is established. It is often necessary carefully to continue the use of mercury for a long period, generally in the form of small doses of the perchloride combined with iron; and it is chiefly when this has been done that some small vestige of vision is saved out of the wreck. The lens, in such cases, often becomes coated by lymph, and ultimately requires removal; and it may be necessary to perform iridectomy for closure of the pupil more than once, in consequence of the tendency of the artificial opening to be drawn together again by contraction. On account of the severity of sympathetic ophthalmia, and of its generally unfavourable termination, it is a rule of practice to anticipate its occurrence, and to remove a diseased or injured eye which is likely to produce it, before the mischief has been done.

**V. Diseases of the Crystalline Lens** are separately treated of under the article **CATARACT.**

**VI. Glaucoma.**—In its modern significance, this word is applied to denote all the conditions which are produced by a morbid increase of tension within the eye—that is to say, by an excess of its contained fluids; and the different forms of the affection are mainly due to differences in the rate at which the tension increases.

**SYMPTOMS.**—If the increase be rapid, the loss of sight will be rapidly produced, and will be associated with other changes occasioned by sudden interference with the circulation and innervation, and by sudden stretching of the ocular tunics. When, on the other hand, the increase of tension is very gradual, so that the eye has time to become accustomed to the new conditions as they are produced, the symptoms often present a deceptive resemblance to simple atrophy; and these cases were at one time described as 'atrophy with excavation of the optic nerve.' In some of the more acute forms of increased tension, the pupil presents a clouded aspect of a greenish colour; and it was to cases of this class that the word glaucoma (from *γλαυκός*, sea-green) was originally applied, at a time when the pathology of the condition was not understood. When this pathology was rendered clear, and when it became known that the glaucoma of the ancients was in all essential respects identical with cases in which the most manifest symptoms were of a different kind, the word was retained as a convenient general term, to express states of disease to which it had no longer any apparent reference; and hence we still speak of glaucoma, although, in the great majority of the cases in which we do so, the green aspect of the pupil is conspicuous by its absence.

The normal tension of the eye appears to be maintained, in the face of continued internal secretion of fluid, mainly by the transudation of this fluid, at the so-called 'filtration area,' in the angle formed between the cornea and the iris, into the plexus of veins contained in the canal of Schlemm. In order that this transudation may be free, it is necessary that the angle should be open, and the access of fluid to the filtration area unimpeded. In certain relations of the lens to the neighbouring structures, and, possibly, in consequence of increased bulk of the lens in advancing life, the periphery of the iris may be so pushed forward towards the cornea as to produce partial closure of the angle, and impeded access of fluid to the filtration area. Such conditions tend necessarily to increase; and they are liable to be increased still further by dilatation of the pupil, which implies thickening of the peripheral portion of the iris, and the occupancy, by this portion, of an abnormal amount of space. At a later period, as the tension continues to increase, the peripheral portion of the iris may even be applied to the margin of the cornea after the

fashion of a valve, and transudation may be completely arrested.

The estimation of increased tension by the fingers is a matter which requires the *tactus eruditus*, and is best accomplished by directing the patient to close the eyes gently, and to cast them downwards. The tips of the two forefingers should then be placed upon the upper lid immediately below the margin of the orbit, and, when one finger has fixed the eye by holding it gently back against the orbital contents as far as it will recede, the other estimates the degree in which it may be dimpled by slight pressure. This degree varies to some extent in different persons within physiological limits, but a morbid increase of tension can scarcely be missed if it is looked for. Moreover, the diagnosis of glaucoma does not rest upon increased tension alone, but upon the combination of increased tension with decreasing sight. The rate of slow increase which may simulate atrophy, or of rapid increase which may simulate inflammation, are matters of detail which should not, in either case, be suffered to obscure the true nature of the morbid process.

The symptoms of glaucoma depend upon the more or less gradual interference with the ocular circulation, and compression of the ocular nerves, by reason of increasing pressure within the eye. In consequence of the interference with the circulation, the blood enters and leaves the eyeball with difficulty. The first indication of this difficulty is afforded by the small veins which pierce the anterior portion of the sclerotic near the cornea, and course backwards beneath the conjunctiva towards the equator. These veins, which are invisible, or at least inconspicuous, in health, become distended and tortuous when the impediment to the venous outflow reaches a certain degree. At the same time, the ophthalmoscope will usually discover pulsation of the retinal vessels upon the optic disc, a pulsation first observed in the veins, and afterwards also in the arteries. It would seem that the contents of the veins are pushed back by the entering arterial current, and that the latter is only able to make good its way at the acme of the pulse-wave.

The symptoms which depend upon compression of the nerves will vary, of course, with the functions which these fulfil. Commencing with ordinary sensation, a moderate compression of the filaments derived from the fifth produces diminished sensibility of the corneal surface; while a pronounced increase of tension, especially if rapidly produced, occasions severe pain by the stretching of the ocular tunics. Proceeding to the motor filaments, compression of those derived from the third produces paresis of the ciliary muscle and of the sphincter pupillæ; the former evidenced by rapidly increasing impairment of accommodation, the latter by sluggishness and dilatation of the pupil, the

dilatation usually moderate in degree, but often causing the aperture to assume an elliptical outline, with its major axis horizontal. This pupillary dilatation is apt to be increased by the forward pressure of the crystalline lens; and, however produced, it tends, in the way already described, to occasion a still further increase of tension. The compression of the retina causes impairment of visual function, first manifested in the portions most remote from the central blood-supply; and hence taking the form of contraction of the field of vision, usually first displayed and most marked on the nasal side. Contemporaneously with this, central vision will be more or less reduced; and, at the same time, the increasing intra-ocular pressure will occasion yielding from within wherever such yielding is possible, and hence chiefly over the area of the optic disc, the structures composing which will be to some extent pushed back out of the eye, leading to the formation of a 'cup' or excavation, which is one of the most conspicuous of the ophthalmoscopic signs of heightened tension. Finally, the general nutrition of the eyeball will suffer, in a manner which is often first displayed by the surface epithelium of the cornea, which is apt to become disturbed, irregular, or, as it were, 'steamy,' presenting an aspect somewhat as if it had been breathed upon, and constituting a cause of further serious impairment of the already diminished vision.

Such being the chief symptoms, one or more of which will be recognisable by examination in glaucoma, those complained of by the patient are often exceedingly characteristic. Glaucomatous tension is apt to increase in waves, separated by intervals in which it may decrease, or in which the structures pressed upon acquire some tolerance of the new conditions. We therefore often hear complaints of sudden 'clouds' or 'obscurations' of vision, which pass away after a few minutes or a few hours, and return at uncertain intervals. The intervening recovery in such cases is seldom complete; each 'cloud' usually leaving the sight permanently worse than before. The depth of the cloud, the period of its duration, and the presence or absence of pain, are conditions which will be governed by the extent and the rapidity with which tension has been increased. When the cloud has passed away, we shall usually find diminution of central vision, contraction of the field, especially on the nasal side, and sluggishness of the rather large pupil. At the same time, it will often be found that the sensitiveness of the corneal surface is diminished; and the patient will often admit, on inquiry, that artificial lights of feeble intensity—candle flames, for example—are frequently surrounded by coloured halos. But the combinations and the order of occurrence of symptoms will differ widely in

different cases; and all that can be called essential, in order to constitute glaucoma, is a combination of impaired central vision and diminution of the field, with increased tension discoverable by the educated finger. When this combination is present, there should be no doubt as to the diagnosis, as there will certainly be no time to waste in inefficient treatment.

**TREATMENT.**—The treatment of glaucoma is entirely surgical, the affection being capable of arrest by iridectomy or sclerotomy in the great majority of cases. In the more acute forms, an operation, if performed sufficiently early, usually restores vision to its integrity; but the time during which this can be done is limited, and in the more chronic forms no operation will do more than preserve what amount of sight is still retained. Hence it is important that treatment should not be delayed by any error of diagnosis; and the points to which attention should chiefly be directed, in any case of impairment of vision in which the question may arise, are increasing hardness of the eyeball as determined by palpation, and gradual contraction of the field of vision. Whenever the eye is becoming harder, and the circumferential extent of vision is narrowing in, the case is one in which an operation should be accomplished with as little delay as possible. At the same time, until the operation can be performed, a four-grain solution of eserine should be applied every four hours; this drug having a marked effect in controlling and diminishing tension, and being apparently indebted for this power to its mechanical action upon the iris, which, by the contraction of the pupil, is thinned out and drawn away from the filtration area. It is hardly necessary to add that in any case of actual or threatened glaucoma, the use of a mydriatic would be highly dangerous. The more acute cases of glaucoma are attended by much pain from the distension of the ocular tunics, and often by congestion and inflammation, the results of this distension; and such cases were at one time described as ‘acute internal arthritic ophthalmia,’ or by some similar name. Vision has been irretrievably lost, in hundreds of cases, by endeavours to control this form of glaucoma by medical treatment, to the neglect of operation; and the erroneous practice has been kept alive by the circumstance that some of the cases will undergo partial and temporary amendment. In such circumstances, however, the vision never rises to the degree of acuteness which existed prior to the attack, and the amendment is never more than temporary. Another increase of tension soon occurs; and, without surgical aid, blindness sooner or later closes the scene.

**VII. Diseases of the Optic Nerve and Retina.**—As shown by the ophthalmoscope, these diseases cover a very wide

field of pathology. In order to understand them accurately, it is necessary to bear in mind the anatomy and relative arrangement of the affected tissues. The optic nerve in the orbit is invested by a double sheath, and the interval between the layers of this sheath, which is continuous with the sub-arachnoid space, terminates in a *cul-de-sac* towards the eyeball, the two layers becoming intimately united where they blend with the sclerotic. At this point, the opening in the sclerotic for the admission of the optic nerve is crossed by a film of perforated connective tissue, the *lamina cribrosa*, with which the sheaths of the nerve-fibres blend, or in which they are lost, so that the nerve anterior to the lamina consists of a bundle of unsheathed fibres, enveloping the central artery of the retina, which enters the eye with them, and the central vein of the retina, which passes out in the same position. On entering the eye the nerve-fibres bend round to form the anterior layer of the retina, which contains also the retinal blood-vessels almost to their ultimate divisions, together with some delicate connective tissue. The capillary circulation of the nerve itself is derived from the anterior cerebral artery, and is distinct, save for a very slight amount of anastomosis, from the capillary circulation of the sheath, which is fed by the arteries of the pia mater. It follows that hyperæmia of the sheath, or of the circle surrounding the nerve, may exist without hyperæmia of the proper nerve-tissue, and it has been supposed that fluid pressure in the intervaginal space may interpose an obstacle to the circulation in the vessels which pass through the sclerotic foramen, and may thus occasion dropsy of the termination of the nerve within the eye. Of the two foregoing conditions, either may undergo resolution harmlessly, or may produce such changes in or around the nerve as to occasion atrophy and loss of sight. Neither of them interferes with sight directly, because the circulation may be seriously disturbed by a degree of pressure which is insufficient to stop the conduction of impressions through the nerve-fibres. There is yet a third condition, properly called optic neuritis, or *neuritis descendens*, in which the capillary network of the nerve itself participates in changes propagated downwards, and in which impairment of vision holds a very early place among the symptoms.

1. *Perineuritis.*—The true perineuritis, in which the unchanged nerve-disc is surrounded by a zone of high vascularity, is only seen as a result of meningitis, which may be either tubercular or due to other causes. It was at one time hoped by Bouchut, by whom this especial phenomenon was first described, that perineuritis might serve as a diagnostic sign in cases of doubtful meningeal inflammation; but this expectation has not been realised. The perineuritis itself has only

been observed in cases the character of which was scarcely doubtful, and which, in most instances, have terminated fatally. Very probably, however, it would be found, if looked for, in those cases of exanthematous and other fevers which are attended by cerebral symptoms, followed after recovery by impairment of vision. In these we eventually find, as a rule, a partial nerve-atrophy, which does not lead on to complete blindness, but which does not appear to be susceptible of improvement; and this partial atrophy may no doubt be due to the pressure of perineural exudation during its contracting stage.

**TREATMENT.**—The treatment of perineuritis must generally be that of the affection in which it has its origin; but, in any fever in which this symptom had been detected, it would be a question whether mercury should not be cautiously administered for a considerable time after convalescence, in order to promote the absorption of any effused lymph by which the optic-nerve entrance might be constricted.

2. *Choked Disc.*—**SYNON.**: Dropsy of the Optic-Nerve Entrance.—This is a condition chiefly seen in connexion with intracranial tumours, whether syphilitic, tubercular, or of some other kind; and it almost invariably affects both eyes. It was formerly supposed to be due to the pressure of fluid driven down the intervaginal space around the nerve, and so constricting the latter at the terminal *cul-de-sac* as to impede the outflow of venous blood. This hypothesis is not now universally accepted, but the condition visible with the ophthalmoscope is one of distension and tortuosity of the retinal veins; arrest of the capillary circulation; impediment to the arterial inflow; dropsical effusion into the disc-tissues; and, sometimes, secondary inflammatory changes, such as effusion and cell-proliferation, comparable to the erythema which occurs in the integument of a dropsical limb. All these changes may exist without impairment of vision, because they neither affect the perceptive layer of the retina, nor arrest the conduction through the nerve-fibres. At a later period, however, when any plastic elements in the exudation begin to undergo contraction, the interference with the circulation becomes more complete, the nerve-fibres themselves become compressed, and then failure of sight commonly occurs. At the same period, the nerve passes into a state of atrophy from the interference with its circulation; and these cases of nerve-atrophy were once sources of great perplexity to surgeons, and were referred to alcohol, tobacco, and to other causes which probably had very little to do with them. In consequence of the sight not being affected during the preliminary stage, the occurrence of this stage was for a long time absolutely overlooked, and was only discovered when physicians began to use the ophthalmoscope, as

an ordinary instrument of diagnosis, in all cases of cerebral affection. It was then soon established, notably by the labours of Drs. Hughlings Jackson, Buzzard, and Clifford-Allbutt, that the atrophy had been preceded by swelling of the disc and by obstruction of its circulation; and it was shown before long that the cases of atrophy which had this history were recognisable, after the swelling had passed away, by the tortuosity of the retinal veins which was left behind, and by the way in which these veins were lifted into bold curves at the margin of the disc; this alteration of their original course having been due to the swelling, and remaining after the swelling had subsided. The contraction of the effusion, and the consequent atrophy of the nerve-fibres and closure of the capillary vessels, would be likely to occur earlier in some parts of the disc than in others; and hence, at the time when commencing failure of sight first induced the patient to seek advice on account of it, the disc was commonly seen to be invaded by sectors of whiteness, but to retain its vascularity, or perhaps more than its normal vascularity, in other parts; while, at the same time, the sight was first lost in those regions of the retina the fibres from which were first compressed. Hence it follows that a partial invasion of the disc by atrophic changes, and a partial invasion of the field of vision by blind portions, are among the earliest symptoms in cases of the class under consideration; and these symptoms were at one time referred rather to the nervous centres than to the retina or the disc itself, to changes in which they are now attributed. A not uncommon clinical history in such cases is that there has been constitutional syphilis, imperfectly treated, and ultimately producing headache or other cerebral symptoms, which have probably called for the administration of iodide of potassium and have been relieved by it. Some weeks afterwards there is for the first time a complaint of failing sight; and then the ophthalmoscope reveals that the discs are passing into atrophy, that the retinal veins are lifted into prominent curves at the disc-margins, and that their further course over the retina is generally serpentine. In many cases, the recovery of the patient, as far as general health is concerned, leaves the precise character of the intracranial mischief doubtful; but, in fatal cases, a tumour is the morbid condition most frequently discovered. **See OPHTHALMOSCOPE IN MEDICINE.**

When the merely passive dropsical effusion into the disc becomes complicated with inflammatory changes, as results of the disturbance of the tissues, the sight begins to fail before atrophic changes become manifest; and such cases are very difficult to distinguish from those in which there is *primary or descending neuritis*. The blood-supply of the optic nerve being derived from

the anterior cerebral artery, we may reasonably expect to find capillary engorgement of the nerve-substance of the disc in connexion with arterial hyperæmia of the brain; and this capillary engorgement may pass into inflammation, either of local origin or by transmission downwards from above. In any case, if the first changes in the disc are of the character of neuritis rather than of obstruction, we see capillary or arterial hyperæmia of the nerve-substance rather than venous congestion; and effusion of plastic material upon the disc itself, with comparatively little prominence or disc-swelling, and with comparatively little extension over the disc-margins upon the surrounding retina. At the same time, even in the early stage of the affection, we find great impairment of sight, the conducting power of the nerve-fibres being seriously injured. Such cases are frequently syphilitic, and, unless the absorption of the effusion should be quickly brought about by treatment, its contraction, like that of the effusion of obstruction, soon occasions atrophic changes. In these cases, however, the swelling having been absent or inconsiderable, the vessels do not show that elevation into bold curves at the disc-margin which has already been described; and the contraction being interstitial in the nerve-substance, and from the first affecting veins and arteries in an equal degree, the arterial inflow is diminished *pari passu* with the diminution of the vein-channels, and the latter vessels are seldom distended in such a manner as to render them distinctly varicose or tortuous. The ultimate result is a white disc, on which the arteries and veins are dwindled to threads, or at least greatly reduced from their normal calibre.

We may therefore have three conditions which in their typical forms are tolerably distinct, but which are prone to run into one another by almost imperceptible gradations, and which may all lead on to atrophy and complete blindness: namely, perineuritis, neuritis, and choked disc. The liability to the last-mentioned condition should be carefully remembered by physicians, and should lead to careful ophthalmoscopic examination in all cases of obstinate headache or other cerebral symptoms of obscure origin, more especially in a patient with a syphilitic history.

**TREATMENT.**—It is manifest that the best hope of preventing ultimate blindness in persons in whom choked disc has occurred will be secured by the administration of medicines calculated to assist the absorption of the effusion, and by continuing these medicines, with comparatively small reference to the general symptoms, until the discs have cleared. The writer has seen such clearing occur, without loss of sight, in circumstances which rendered it almost certain that neglect of the disc-effusions would have been followed by blindness at no distant

date. The same general rule will apply, of course, to the more directly inflammatory effusions of neuritis or perineuritis; and, when we find any one of the three conditions passing into atrophy, or when we find commencing atrophy in discs which show traces of past effusion, the principle of treatment is to endeavour to promote the absorption of any contracting material which may be the physical cause of the atrophy; and then, when this has been done, to seek to stimulate the nutrition of the nerve-fibres, and to assist them to recover from the shock which they have sustained. The mode of fulfilment of the first indication must depend mainly upon whether there is a history of syphilis, and, if so, upon the manner in which it has been treated. In the numerous cases in which a short course of mercury has been administered, enough to alleviate secondary symptoms, but wholly insufficient to eradicate the disease, it will generally be desirable to give iodide of potassium in full doses for a time, and to follow this by the prolonged administration of the perchloride of mercury, in the hope of really curing the patient. There are, in the writer's opinion, few things better worth remembering in therapeutics than that the iodide, immeasurably the most valuable drug which we possess as a remedy for a late syphilitic symptom, is, none the less, almost useless as a remedy for constitutional syphilis. It will remove the present symptom, speedily and often completely; but it can scarcely be said to have any tendency to prevent the recurrence of syphilitic symptoms at a future time, in the same or in some different form. For this purpose, the only trustworthy agent is mercury; and therefore, while the administration of the iodide for a sufficient time, and in sufficient quantities to test its power of doing good, will be enough in the cases in which syphilis is neither known nor suspected, the iodide must be followed by mercury whenever a syphilitic history of the affection is either clear or highly probable. The second indication, to stimulate the nutrition of the nerve-fibres, is usually best accomplished by strychnine, given at such intervals and in such doses as to produce evidence of its constitutional effect before its administration is abandoned. It may perhaps be most effectually given by hypodermic injection; but this is a point which must be settled in accordance with the circumstances of the case in each individual instance. During the last two or three years, in cases of great disc swelling with impairment or loss of sight, the writer has on four occasions incised the sheath of the optic nerve behind the eye, so as to give exit to any accumulation of fluid in the intervaginal space, or to release an inflamed nerve from the pressure of its unyielding covering. The results have been generally satisfactory; and in one of the patients, who had been totally

blind for several days, vision was completely restored.

3. *Toxic Amblyopia. Toxic Central Neuritis.*—Much attention has been bestowed of late years upon a form of gradual failure of vision which first affects chiefly the central portions of the retina, and which appears to depend upon a chronic neuritis attacking originally the portion of the optic nerve-trunk which contains the fibres destined for the region of the macula lutea. This affection has often been connected with the excessive use of the stronger forms of tobacco, as well as with the abuse of ardent spirits, or with both these conditions in combination. It is characterised by impairment of sight, and also of colour-sense, the impairment being at first limited to the central portion of the field, and the colour-sense often becoming changed before form-vision is very noticeably affected. It may extend, if neglected, over the whole of the nerve-fibres, and may ultimately lead to practical, but seldom to absolute, blindness, perception of light and of large objects being often retained. In order to test for central loss of colour-sense, it is necessary to be provided with small red and green objects which may be moved in succession over various parts of the field, and which, in typical cases, will appear much less bright in the centre than when they are held a little to one side of the direct line of vision.

TREATMENT.—This consists, firstly, in the abandonment of tobacco and alcohol; secondarily, in endeavours to improve the general health; thirdly, in the use of medicines, such as iodide of potassium and mercury, by which chronic inflammatory conditions are likely to be controlled; and, lastly, in stimulation of the weakened nerves by the careful employment of strychnine. A very careful prognosis should be given in the first instance; but, if improvement once commences, the case will usually terminate in recovery.

4. *Sclerosis of the Optic Nerve.*—Besides the consecutive forms of atrophy above enumerated, there is yet another of common occurrence, which is either a primary sclerosis of the optic nerve, or a sclerosis secondary to a similar affection of other parts of the nervous centres. This form of atrophy is not preceded by effusion, nor is it attended by any marked decrease in the calibre of the central vessels of the retina, even when the capillary circulation of the disc has almost wholly disappeared. It is often seen in connexion with disease of the spinal cord, as in locomotor ataxy; and also occurs in apparently healthy people, seemingly as a purely local affection.

Sclerosis is easily distinguished from the atrophies consecutive to effusion, whether active or passive, by the circumstance that the effusion, as it undergoes contraction, tends to render the nerve-tissues opaque as

well as to bleach them, and thus leaves a disc-surface of an almost ivory whiteness and of uniform colour. In sclerosis, on the other hand, the nerve-tissue disappears to a great extent, and reveals the mottled surface, often of a bluish-white tint, of the lamina cribrosa. When this is plainly seen, and when, at the same time, the vessels are neither much diminished in calibre nor altered in their normal curvatures, sclerosis may be assumed to exist; and this form of atrophy may also be distinguished from that which is produced by the most chronic forms of glaucoma, by the circumstance that in the latter the vessels bend into the excavated disc at its margin, while in the former they pass over the margin in straight lines or nearly so. Chronic glaucoma would also usually be distinguished by the character of the failure of sight, which would be marked by the ordinary contraction of the field of vision, even when central vision was only a little impaired; and also by the gradual hardening of the eyeball, which would be present in glaucoma and absent in nerve-sclerosis. Still it cannot be denied that this particular diagnosis is not without its difficulties, and that in certain cases it has given rise to differences of opinion between men of large experience on all sides of the question at issue.

The diagnosis is important as well as difficult, since the mischief of glaucoma may admit of arrest by iridectomy or sclerotomy; so that to mistake chronic glaucoma for atrophy, and to neglect operation, may be to condemn the patient to unnecessary blindness. The opposite error can at least do no harm; and therefore, whenever a doubt really exists upon the point, the most proper course is to give the benefit of that doubt to the patient, and to advise the performance of an operation which cannot injure, and which may relieve him. The atrophy of sclerosis scarcely admits of treatment, but it may perhaps sometimes be delayed, or even prevented from becoming complete, by the administration of full doses of strychnine and iron.

5. *Atrophy from other causes.*—Besides the foregoing forms of atrophy, there is a variety which appears to be associated with chronic lead-poisoning, and in which the discs may acquire a peculiar grey or bluish tint; and the optic nerves may also undergo secondary wasting in consequence of other conditions presently to be mentioned, such as obstruction of the central artery by an embolus, or the long continuance of pigmentary retinitis.

6. *Retinal Hæmorrhage.*—The chief disorders of the retinal circulation displayed by the ophthalmoscope are hæmorrhages, which may be attended by very different circumstances, and may present widely different characters.

a. *Single.*—When blood proceeds from one of the larger veins of the retina, which yield

a considerable quantity, and which are situated immediately underneath the limiting membrane, the hæmorrhage usually spreads out over the fundus as a red patch of uniform colour and aspect, and vision is suddenly, and sometimes almost totally, obscured. The writer has seen such bleeding occur from the yielding of a vessel during parturition; but this accident is extremely rare, and the large hæmorrhages in question are certainly more common in women at the period of cessation of the menstrual function than in any other circumstances. At this time, and when the health is not seriously affected, a favourable prognosis may be given with some confidence; for the blood will before long be absorbed, and restoration of vision, at least in a considerable degree, may be expected. The writer has once seen complete restoration to the normal standard, but this is an exceptional occurrence.

**TREATMENT.**—The only treatment necessary is to pay attention to the requirements of the general health; and to prescribe such diet, medicines, regimen, and habits as may tend to calm and equalise the circulation, and to prevent local congestions. The occurrence of sudden loss of sight in one eye will justify the suspicion of hæmorrhage; but the suspicion can only be converted into certainty by the ophthalmoscope.

*b. Multiple.*—A form of venous hæmorrhage which at first seems less formidable, because it is attended by a smaller degree of immediate interference with sight, but which calls for a less favourable prognosis, is that in which the hæmorrhages are multiple, often singly of small size, and scattered over the whole fundus of the eye. The appearances which they present differ, apparently in accordance with their precise position in the retina. If they proceed from vessels which are superficial, the blood is spread out, as in the last variety, in round or oval patches beneath the limiting membrane; but if the vessels lie a little deeper, and are fairly engaged in the fibre-layer, the blood will separate the fibres and find its way between them, forming flame-shaped or brush-like patches, which are often very numerous. Such multiple hæmorrhages are very slowly absorbed, and have a tendency to recur; so that they must always be regarded as placing the sight in serious jeopardy. They are often monocular, and they do not point to any definite disturbance of the general health. The only endeavour so to connect them with which the writer is acquainted was made by Mr. Hutchinson, who described some cases of flame-shaped hæmorrhage in persons all of whom he said were 'gouty'; but it will certainly be the experience of most practitioners that flame-shaped hæmorrhages occur in many patients who are not 'gouty' in the ordinary sense, and that they do not occur in vast numbers of those about the

reality of whose gout there can be no question. The presence of multiple hæmorrhages is sometimes attended by a considerable degree of irritation, or even inflammation, in the tissues among which the blood has been effused; and this condition, in which the retina between the blood-spots may become opalescent or turbid, has been described as a form of retinitis—*retinitis apoplectica*. The element of inflammation, in such instances, is probably merely a reaction consequent upon the injury inflicted upon the tissues, and it cannot be inferred that the bleeding is itself the result of any inflammatory process.

**TREATMENT.**—In this, as in the former variety, there is no special indication for treatment, which must be confined to the correction of any manifest disorder of the general health, followed, in most instances, by the administration of iodides or bromides, as medicines calculated to assist in the absorption and removal of the effused products. Any indication of a general hæmorrhagic tendency, or of a state allied to purpura or scurvy, would require, of course, full consideration and appropriate treatment. The extent of the ultimate injury to sight will usually depend upon the extent to which the perceptive elements of the retina have been compressed or disorganised, either by the bleeding itself, or by other changes consecutive to it.

*c. Arterial.*—Hæmorrhages which are distinctly arterial are not uncommon in the fundus of the eye, and can generally be distinguished without difficulty from the venous variety, not only by the colour of the effused blood, but also by the situation of the blood-patch, and by its manifest relations to a small arterial branch, which may often be seen to have dwindled or closed beyond the point at which it has given way. Arterial hæmorrhages are mostly multiple, but of small individual extent; and, when not in the immediate neighbourhood of the optic disc, are most commonly seen near the outer limits of the ophthalmoscopic field of view. They are generally attended by sufficient impairment of vision to occasion complaint, and thus to lead to their detection; but they seldom occasion blindness. They call for an examination of the urine for albumen, and, failing any evidence of renal mischief, they are chiefly important as indications of a weakened and brittle state of the arterioles, likely to lead to intracranial hæmorrhage.

**TREATMENT.**—Arterial hæmorrhages into the retina point to the necessity of diminishing, as much as may be possible, the strain upon the arterial coats, by such means as the avoidance of muscular exertion or mental emotion, and by seeking to diminish the quantity of the circulating blood by a diminution in the quantity of fluid ingested. Even when all precautions have been taken, arterial

retinal hæmorrhages are common forerunners of apoplexy.

7. *Embolism of the Central Artery of the Retina.*—Embolism of the central artery of the retina, or of one of its branches, is a condition of not infrequent occurrence.

SYMPTOMS.—When sudden blindness of one eye occurs in a person who is the subject of valvular disease of the heart, the diagnosis can scarcely be doubtful; but the ophthalmoscopic appearances will suffice to remove doubt if it should exist. The immediate effect of the sudden arrest of the arterial circulation of the retina is to render that membrane opaque and of a milky whiteness, except over the macula lutea, where the absence of connective tissue prevents any such change from being produced. Here, and here only, the original transparency is retained, and the colour of the choroid is still visible, with the result that the macula appears as a cherry-red spot in the midst of a white surface. When not concealed by the opacity, the larger veins of the retina are diminished in calibre and contents, and their blood is sometimes broken up into detached portions separated by interspaces. The arteries are empty, and are either invisible or traceable as white lines of fibrous tissue in the general milkiness of the fundus. The disc is usually bleached, but it will sometimes happen that its condition may be temporarily obscured by arterial hæmorrhage, occurring from some twig given off just below the seat of the embolus, and entering the eye independently.

The driving home of the embolus will throw upon such a twig the whole force of the circulatory *vis a tergo*, and may thus rupture it—an occurrence of which the writer has seen several examples. The blood so effused is usually absorbed in a very few days, revealing the white disc and the collapsed arteries, and removing any uncertainty which might have existed with regard to the diagnosis. The opalescence of the retina also disappears before long, and then only the secondary nerve-atrophy and the disappearance of the arteries remain to disclose the nature of the original affection. Embolism seems to be a perfectly hopeless condition, because there is no anastomosis between the retinal and other vessels of a sufficient extent to maintain a collateral circulation. The writer has met with one instance in which only a sector of the field was affected, and with one in which embolism of a very small branch produced loss of sight over all the peripheral parts of the field, leaving central vision almost intact; but such cases are among the curiosities of ophthalmology, and complete and permanent loss of sight of the affected eye is the result which must always be anticipated.

8. *Retinitis.*—Retinitis is commonly described as occurring in three chief forms—the *albuminuric*, the *syphilitic*, and the *pig-*

*mentary*; but the writer is inclined to believe that only the last of these three is a genuine retinitis, and that in the others the inflammation, if it should exist, is merely a secondary consequence of the irritation produced by the presence of adventitious deposits.

a. *Albuminuric Retinitis.*—In the so-called albuminuric retinitis, the sequence of events appears to lend support to the contention of the late Sir William Gull and Dr. Sutton, to the effect that the renal disease is not an original affection, but only a result of morbid or degenerative changes which are common to the whole of the small arteries of the body.

SYMPTOMS.—In many cases of albuminuria, the sight is not affected from first to last, and the retina remain healthy. In some, the retinal changes precede the appearance of albumen in the urine; and, in the majority, the renal and retinal changes are coincident. The retinal changes are of two kinds: namely, arterial hæmorrhages, occurring in the fibre-layer, so that the blood-patches assume a fibrillated aspect with brush-like terminations; and the formation of white patches, either of cholesterine deposit or of fatty degeneration, or of both combined, scattered irregularly over the fundus, but often grouped into a stellate figure around the macula lutea, and into an irregular ring around the disc. To these appearances are added, in some cases, those of swelling of the disc-margins with effusion into the retinal fibre-layer; and, when the last-named appearances are presented, there is always a far greater deterioration of sight than when they are absent. It is a matter of daily occurrence that the existence of renal disease is not suspected until impairment of sight leads to an ophthalmoscopic examination, and this to the discovery of the retinal changes; and, in every hospital, cases which apply for relief to the ophthalmic department are constantly, on this ground, transferred to the physician.

TREATMENT.—The treatment of the renal maladies which produce albuminuria is in no way modified on account of the presence of a retinal complication; and the unfavourable prognosis which must generally be given as regards life throws into comparative insignificance the gradual failure of vision, which seldom proceeds to complete blindness.

b. *Syphilitic Retinitis.*—This is usually an incident of the most advanced stages of the disease, and is most frequently seen in persons who have been inadequately treated during the primary stage, but who have for some months or even for a year or two been free from symptoms.

SYMPTOMS.—Dimness of sight is then complained of, and the retina is found to present scattered patches of very irregular outline, and of a filmy whitish aspect. Such patches may be more or less obscured by slight

general turbidity of the retina itself, or of the vitreous body in its immediate vicinity, the latter condition being of itself almost conclusive of the nature of the malady.

**TREATMENT.**—The treatment must be greatly governed by the past history of the case, but may in most instances turn upon the use of iodide of potassium for the relief of the retinal troubles, followed by a sufficient course of mercury for the eradication of the syphilitic taint.

*c. Pigmentary Retinitis.*—This appears to be a true inflammation of the retina, differing from the foregoing affections in that it attacks the percipient elements, instead of the fibre-layer or the connective tissue of the membrane.

**ETIOLOGY.**—The subjects of pigmentary retinitis are of all ages, from nine or ten years to seventy; and, in some instances, the duration of the disease has been as much as twenty years, from the first appearance of the symptoms to their ultimate termination in blindness. As a rule, however, the patients are young adults, or persons not past middle age.

It is a remarkable feature of pigmentary retinitis that it almost invariably attacks more than one member of a family; and it has been said to be especially frequent in the offspring of marriages of consanguinity, but this statement is not borne out by English experience. During the last twenty years the writer has only met with one family in whom the malady had this history.

**ANATOMICAL CHARACTERS.**—From the extreme chronicity of its course, from its obstinacy, and from its peculiar anatomical distribution, pigmentary retinitis should probably be regarded, together with some forms of choroiditis, as having its analogies among some of the chronic diseases of the skin. It usually appears to commence in a narrow annulus near the equator of the eyeball, and gradually spreads inwards towards the optic disc; the tissues affected are the percipient and pigmentary layers of the retina and the subjacent chorio-capillaris, which slowly become disorganised and matted together in one common degeneration. Coincidentally with the progress of the disease, pigment is deposited in the parts affected, and in the retina superficial to them, in the form of irregular lines and striations, and especially along the course of the main arterial branches. As the annulus of disease gradually closes in upon the macula, the optic disc undergoes atrophy of a kind which gives it a peculiar tint of whiteness, very readily recognisable when it has once been noticed, and the central vessels, both veins and arteries, dwindle in size.

**SYMPTOMS.**—The subjective symptoms are as characteristic as the ophthalmoscopic appearances. Over the region actually invaded, the percipient elements of the retina are de-

stroyed, and the power to receive visual impressions is lost. The fibre-layer not being implicated, the conduction of impressions from parts of the retina more peripheral than the disease may remain unaffected; and hence we may have a blind zone surrounding the centre of the field of vision, and surrounded itself by a zone still more external, in which dim vision is preserved. But the salient symptoms are two—the gradual contraction of the field of vision due to the progressive encroachments of the disease; and night-blindness, due to the nerve-atrophy, which interferes with the conduction or perception of any but strong impressions. When these symptoms co-exist; when the field of vision is small and becoming gradually smaller; and when the patient, who can still see fairly in the daytime, can scarcely find his way about as dusk begins to fall, we may predict the ophthalmoscopic appearances with a very near approach to certainty. The optic disc will be unnaturally pale, and the fundus overstrewn, towards the periphery, with irregular black lines and stripes, of which it is quite possible that none may be visible within that portion of the field of the ophthalmoscope which includes the disc.

**DIAGNOSIS.**—Pigmentary retinitis may possibly be mistaken for the most chronic form of glaucoma, on account of the contraction of the field of vision; but it may be distinguished by the absence of high tension, by the night-blindness, and by the pigmentation of the retina. It may also be mistaken for the atrophy of sclerosis, but only if the ophthalmoscopic examination is limited to the nerve-disc, to the exclusion of the surrounding parts of the fundus.

**TREATMENT.**—In the treatment of a disease so essentially chronic, it is difficult to arrive at any trustworthy evidence concerning the efficacy of a remedy, but the prolonged administration of iron, rather as a food than as a medicine, is at least of a certain degree of utility in arresting the progress of the malady. The preparation employed is probably not material, and some may be found to suit particular persons better than others; but the writer is accustomed to begin with the tincture of the perchloride, in doses of five minims, well diluted and given three times a day as part of a meal.

*9. Detachment of the Retina.*—**SYNON.:** Subretinal Dropsy.—This is a condition the causes of which have never been satisfactorily explained, but it has been attributed to the contraction of inflammatory effusions in the vitreous body, which have been supposed thus to exert traction on the retina.

The first symptom which attracts the attention of the patient is the loss of part, usually either the upper or the lower part, of the field of vision; and it is manifest that loss of the upper part of the field means detachment of the lower part of the retina, and

*vice versâ*. Detachment is sometimes produced by a blow or injury, but more frequently it occurs without any assignable cause, either local or constitutional. One or both eyes may be affected.

The diagnosis of the disease is rendered easy by the ophthalmoscope, which exhibits the detached portion as a sort of floating prominence, projecting into the interior of the eyeball, generally bluish-white in colour, and crossed by the retinal blood-vessels.

The prognosis is very unfavourable in the majority of instances, and treatment is seldom effectual.

**TREATMENT.**—Cases have been recorded in which disappearance of the sub-retinal fluid, and restoration of vision, have followed prolonged confinement in the supine posture; and the occurrence of improvement after spontaneous rupture of the detached portion suggested to von Graefe the advisability of producing such a rupture by artificial means. Various operations have been undertaken for this purpose, and also for the evacuation of the sub-retinal fluid through a puncture in the outer tunics of the eye, and have in a few instances been partially successful; but the evidence in their favour is at present very feeble, and hardly establishes more than that attempts of such a nature may be made, if it is certain that the sight will be irretrievably lost in the absence of interference. The writer once obtained an excellent result by puncturing a detached retina in an eye from which cataract had been removed eleven years before; but the puncture was greatly facilitated, and its risks were in a corresponding degree diminished, by the absence of the lens. Two or three years later, however, the detachment returned and became complete. The tendency of detachment, especially in the upper portion of the retina, is to increase until the whole membrane is elevated from the choroid, and vision is entirely destroyed. It must be borne in mind that detachment may be simulated, or may even be caused, by the growth of intra-ocular tumours, sarcomatous or gliomatous, which may demand the early removal of the eyeball. Such cases would usually be distinguished from simple detachment by the increased hardness of the eyeball, which the morbid growth almost necessarily occasions, and which would be the more significant inasmuch as detachment alone is usually accompanied by diminished tension. It must nevertheless be remembered that normal tension does not absolutely preclude the presence of tumour; as there are well-authenticated cases in which the absorption of the ocular fluids has, for a time, precisely kept pace with the increase of the growth.

10. *Glioma*.—This name has been given by Virchow to a malignant growth which has its origin in the neuroglia, or connective tissue of the nervous system, and which was formerly

described as encephaloid cancer. When originating in the retina, it early produces loss of sight, and presently shows through the pupil as a substance of a primrose-yellow colour, by which the still transparent lens is pressed forward towards the cornea. It is chiefly a disease of childhood, and has been seen by the writer as early as the fifth week of infant life. It is liable, by superficial observers, to be mistaken for congenital or infantile cataract, an error which must be carefully guarded against, because the early and entire removal of the eye, together with as much of the optic nerve as can be reached, furnishes the only hope of preserving the life of the patient. When the operation is performed sufficiently early, it has in a few instances been completely successful, cases having been recorded in which no recurrence of cancer has happened after the lapse of years. In the great majority, however, recurrence and death have terminated the history.

11. *Sarcoma*.—This differs from glioma in having its origin in the choroid, and in being of a darker colour, and sometimes pigmented or melanotic. It is at least equally malignant, produces similar symptoms, and requires the same treatment.

**VIII. Diseases of the Choroid.**—Diseases of the choroid, recognisable by the ophthalmoscope, are almost limited to certain chronic forms of inflammation and of atrophy; for, in any acute choroiditis, there is always too much turbidity of the vitreous body to allow the state of the membrane to be seen.

*Chronic Choroiditis.*—The chronic forms of choroiditis are remarkable for leading to an undue formation, or to a great displacement, of the choroidal pigment; and to the ultimate complete wasting and disappearance of the portions of the choroid which are affected, so that over these portions there will ultimately be no choroid visible, and the ordinary red colour of the fundus will be replaced by the ivory whiteness of the inner surface of the sclerotic.

Chronic choroiditis may be divided into two chief varieties—the *disseminated* and the *diffused*. The *disseminated* occurs chiefly in children, and chiefly, perhaps exclusively, in those who are the subjects of inherited syphilis. It is seldom seen until its period of activity is passed. A child is brought on account of defective vision, which has probably existed from birth or from a time but little subsequent to it; and the ophthalmoscope displays a number of small white spots, with black borders, scattered irregularly over the fundus of the eye. The white spots are patches of choroidal atrophy, and the black borders are rings of increased pigment-formation, by which the spots of inflammation, which must have been comparable to little pimples, have been surrounded.

**TREATMENT.**—Such cases admit of no treat-

ment, except in the rare instances in which some active mischief may be detected, in the shape of small patches or spots in which effusion has not yet passed into atrophy, and in which such an antisyphilitic treatment should be employed as the state of the patient may otherwise permit or indicate.

*Diffused choroiditis* is more frequently an affection of adult age; and, although very frequently syphilitic, is not invariably so. It differs from the foregoing chiefly in the absence of any defined shape or precise limitation of the parts affected. In the early stages the choroid is seen to be troubled by congestion or effusion, and these conditions pass gradually into abnormal pigmentation and atrophy. The course of the disease may be very chronic and irregular, and different stages of it may be seen at the same time in different parts of the same eye.

The prognosis may in general be moderately favourable; for, although the choroiditis destroys the portion of retina immediately in front of it, its extension is very capricious, and it may often be arrested in time to leave large portions of the eye, and especially the central portions, unharmed. When it occurs in the vicinity of the macula lutea, so as to imperil central vision, it is much more formidable than when confined to the more peripheral parts of the choroidal membrane.

**TREATMENT.**—Whenever there is a history of syphilis, this must be taken as the clue to treatment; and, if no syphilis can be discovered, the chief reliance must be placed upon rest of the eyes, occasional depletion from the temples by Heurteloup's leech, counter-irritation by blisters or setons, and such internal medication as the general state of the patient may suggest.

### IX. Diseases of the Vitreous Body.

Diseases of the vitreous body are as yet very imperfectly understood, and we know little more concerning them than that this substance is liable to become turbid in certain forms of acute general inflammation of the eye; and that it is sometimes rendered turbid, without inflammation, by the presence of floating films which may be readily seen by the ophthalmoscope, and which may be so numerous as to form a serious impediment to vision.

1. *Turbidity.*—Turbidity of the vitreous is very common in syphilitic cases; but the films referred to are seen when no syphilis can be suspected. Their number, and their free movements, show that the vitreous must in great measure have lost its natural semi-solid consistence, and have become fluid; but little or nothing is known of their actual pathology.

**TREATMENT.**—The most effectual treatment for flocculi in the vitreous is usually diaphoresis by the subcutaneous injection of from two to four minims of a 10 per cent. solution of hydrochlorate of pilocarpine, which may

be repeated on alternate days. Local counter-irritation with iodine may also be practised; and iodide of potassium may be given internally in such doses as circumstances will allow.

2. *Musæ Volitantes.*—A phenomenon referred to the vitreous body is the appearance of the moving particles, or strings of beaded filaments, which are commonly called *musæ volitantes*. True musæ are known by the negative character that the particles which produce them cannot be seen by the ophthalmoscope; and by the positive character that they never so intervene between the eye and an object, however small, as to exclude the latter from view. They are seen most readily against a white field, as a white wall or a white cloud, or in the illuminated field of a microscope when there is no object in view; and they float about with uncertain movements, but always a little out of the direct line of sight. They are occasioned by the filamentous framework of the vitreous body, and by the cell-nuclei or other irregularities upon the filaments. These bodies, without being opaque, yet differ in the precise degree of their transparency from the fluid which surrounds them; and hence they cast upon the retina shadows, which are then mentally projected outwards into space as floating objects. The projected shadows appear, of course, enormously larger than the microscopic specks which produce them, and the latter are wholly unimportant and of no morbid signification. Musæ may be discovered by any person by the simple expedient of looking through a very fine perforation in a metal disc at a bright surface; and they are more conspicuous to some persons than to others, on account of the varying differences which may exist in different eyes or in the same eyes at different times or under different conditions, between the index of refraction of the filaments and nuclei and that of the surrounding fluid. Moreover, by the operation of an obvious physical law, the more distant the particle from the retina, the larger will be its shadow upon that membrane, and the larger and more conspicuous will it appear. For this reason, and on account of the elongation of the myopic eyeball, musæ are usually more complained of by the short-sighted than by others. They are often sources of great uneasiness to patients; but, when once their true character is known, they may be entirely disregarded as harmless appearances, the natural results of physiological structure. It is often important that the physician should be able to make their nature understood, in order that he may dissipate, once for all, the unfounded apprehensions which may be occasioned by their presence.

X. *Diseases of the Eyelids.*—The external surfaces of the eyelids, as parts of the common integument, are liable to all its

diseases, and may thus participate in erysipelatous inflammation, in eruptions, and in the results of injury, besides becoming the seats of *nævi*, moles, warts, and other growths. Among the diseases special to the formation of the eyelids, the most important are the variations of shape to which they are subject, generally from the contraction of inflammatory exudations, but sometimes from perverted muscular action; the cystic tumours which are produced by obstruction of the orifices of Meibomian glands; the inflammation of the follicles of the eyelashes, or blepharitis; spasmodic closure, from abnormal muscular contraction; and either patency or passive closure, from paralysis. Many of these affections are distinctly surgical, and others are only parts or symptoms of more general disorders.

1. *Blepharitis*.—Blepharitis, or inflammation of the follicles of the eyelashes, has received a great variety of names from different writers, and is frequently known as *tinea tarsi*, or, in its more advanced stage, as *lippitudo*. The disease consists essentially of an inflammation of the lining membrane of a hair-follicle from which an eyelash springs.

**SYMPTOMS.**—The first manifest symptoms are a small swelling close to the edge of the eyelid, generally of the upper lid; and the formation of a crust around the bases of the cilia which proceed from the swollen part. The swelling does not extend farther up the lid than to the breadth of about a line, but it soon spreads along the border until the whole length is involved, and it usually spreads also to the lower lid, manifestly in consequence of the contagious character of the discharge. If the crust is removed, and if the part from which it springs is magnified and carefully examined, it will be seen that the mouths of the follicles are somewhat open, no longer fitting closely to the issuing hairs; and, in a few moments, a clear fluid will be seen to exude, and speedily to dry into a crust or film, which covers the opening as if with a varnish. Many of the hairs in the affected follicles are loosened, and fall readily, or may be removed painlessly by slight traction. If the case is neglected, the follicles are before long destroyed as hair-bearing organs, so that the lost cilia are no longer reproduced; and, at the same time, the exudation which constitutes the subcutaneous swelling of the lid-margin begins to undergo contraction, and in this way gradually everts the cartilage of the lid. The edges of the lids become red, swollen, and unsightly; the lachrymal puncta are displaced outwards in such a manner that they can no longer take up the tears; the eyes have lost the protection of the lashes, and are exposed to numerous sources of irritation from atmospheric particles and other causes, so as to be especially prone to conjunctival

and corneal inflammations; and these results are almost incurable. It is therefore very important that blepharitis should be effectually treated in its early stages, when, if only due care be taken in the selection and use of remedies, it is an exceedingly trivial affection.

**TREATMENT.**—The most essential part of the treatment is to remember that the secretion which forms the crust is of such a nature that it is not very easy of removal, and that, while it remains *in situ*, no remedies, however judiciously chosen, can obtain access to the parts really affected by the disease. The crust is composed partly of the already mentioned secretion from the inflamed surfaces, partly of the greasy secretion of the Meibomian glands; and it is the admixture of the latter which renders the crusts difficult of removal by water alone. A solution of bicarbonate of sodium, of the strength of five grains to the ounce of warm water, will remove them readily; and this solution should be applied in such a manner as to soak into the crusts and loosen them thoroughly before any attempt is made to detach them. As soon as they are detached, the surface beneath should be gently dried with a morsel of absorbent rag, and then an astringent should be applied immediately, so that it may find its way down into the depths of the hair-follicles, and may thus reach the seat of the malady. The best astringent is generally the ointment of the precipitated yellow oxide of mercury, or Pagenstecher's ointment, already recommended for the cure of ulcers of the cornea; and this may be applied to the affected part by the tip of a finger. If amendment does not speedily follow, it may be suspected that the crusts have been imperfectly removed, or the applications imperfectly made, and it will be well for the practitioner personally to superintend the process. When this has been done, if the affection continues obstinate, some other astringent should be tried, and the nitrate of silver is among the best for this purpose. Amendment of the lid-margin may generally be quickly produced; but the disease will for a long time lurk in the depths of the follicles, and the treatment must be continued until all subcutaneous swelling has disappeared from the lid-margins. Unless this be done, speedy relapse is inevitable, the inflammation soon creeping out of the follicles again and recovering the ground of which it had been deprived. Such a result is constantly seen in hospital practice, in spite of all efforts to guard against it, and, in prescribing for blepharitis, it is always desirable to warn parents of the perseverance which will be required, and of the great importance of obtaining a radical cure. There can be no doubt that blepharitis is exceedingly contagious through the medium of its secretion, conveyed upon sponges, towels, or fingers,

and this should be fully recognised whenever it attacks children who are attending a school. The name 'tinea tarsi' may perhaps be taken as the expression of a belief that the disease is allied to tinea tonsurans, and that it is produced by the growth of a parasitic fungus. The writer does not at present see any sufficient ground for the adoption of this opinion.

2. *Entropium and Ectropium*.—Incurvation and excurvation of the eyelids may be looked upon as purely surgical maladies. The former exposes the eyes to injury from the irritation of inturned eyelashes (*trichiasis*); the latter from foreign bodies of various kinds.

TREATMENT.—The remedy for both, when any is practicable, must usually be sought in a surgical operation. An exception depends upon the fact that ectropium is sometimes produced by paralysis of the facial nerve, which renders the orbicularis muscle flaccid and powerless, and permits the lower lid to fall downwards under the influence of gravity. The cure of the general nerve-affection may restore the power of the muscle, and may in time lead to complete recovery of the natural position of the lid. In such cases, even if electricity does not form part of the general treatment of the paralysis, it may often be applied with benefit to the orbicularis.

3. *Blepharospasmus*.—This term is generally employed to denote an intermittent closure of the eyelids by an involuntary action of the orbicularis, in response to some concealed source of irritation; and is thus broadly distinguished from the spasm which accompanies photophobia.

SYMPTOMS.—The spasm is most liable to occur in circumstances of mental excitement. Thus, in one of the writer's patients, who was a skilful cook, the eyes were apt to close, and to remain closed for some minutes, at the critical period of an important dish. Another patient was a schoolmistress, and the spasm would interrupt the progress of a lesson to a class, being doubtless to some extent excited by the dread of its occurrence. In a third case, the patient being a gentleman habituated to riding and driving, the spasm would be excited by physical irritants, such as wind or dust, and, almost certainly, by circumstances which required the eyes to be wide open as a condition of safe guidance. The motor nerves appear, as a rule, to be merely the passive conductors of a reflected impulse, and the trouble seems usually to be dependent upon a morbid condition of the fifth, or upon a source of irritation in some peripheral part from which a twig of the fifth passes to the centre.

TREATMENT.—In the treatment of such cases, it is sometimes possible to find the twig which conveys the impression; that is to say, to discover a point where pressure, sufficiently firm to arrest conduction, will at once relax the spasm. Such points should

be looked for at the supra-orbital notch, over the malar bone, and in any other situation suggested by special circumstances; and, if a point at which pressure will arrest the spasm is discovered, we learn at once by what branch of the fifth, and therefore approximately from what region, the irritation is conveyed, and where its source is to be sought for. If nothing can be discovered by careful examination, decayed teeth, accumulations of cerumen in the ears, and conjunctival granulations are possible conditions which should be looked for, and which should receive attention if they are found. When all other treatment has failed, the spasm has sometimes been stopped by subcutaneous section of a sensory nerve; and this may always be practised hopefully if the spasm can be arrested by pressure on some definite spot, which must then serve for the guidance of the knife. If no such spot can be found, section of the supra-orbital nerve, and next of the subcutaneous malar, may be attempted; since neither of these is sufficiently important for its temporary disablement to be set against even the possibility of relief from a very distressing affection. In some cases, however, it would appear that the mischief must be central, and that no section of an afferent nerve can be useful. The division of the motor nerves of the orbicular muscles, if it could be successfully accomplished, would produce a paralysis even more injurious than the spasm; and the cases in which the latter is due to central irritation or other trouble, unless they can be relieved by medicine, and by the rectification of whatever may be manifestly wrong in the condition of the patient, offer very small hope of improvement. See FACIAL SPASM.

4. *Ptosis*.—Ptosis is a condition of permanent passive closure of an upper eyelid as a consequence of paralysis of its levator muscle, or it may happen in consequence of this muscle having been torn from its attachment to the tarsal cartilage, so that it can no longer modify the position of the lid.

SYMPTOMS.—Paralytic ptosis may be either partial or complete, according to the degree of the nerve-affection; and as the levator palpebræ is supplied by the third nerve, which supplies also the superior, the internal, and the inferior rectus, as well as the inferior oblique, the sphincter pupillæ, and the ciliary muscle, ptosis is usually accompanied by paralysis of one or more of these muscles. When they are all affected, the eyeball is turned outwards by the action of the external rectus, and is immovable in other directions excepting feebly by the superior oblique. The pupil is dilated, and the power of adjusting the eye for near vision is impaired or lost, although, when the lid is raised, near objects can still be distinctly seen by the aid of a convex lens. When all the muscles supplied by the third nerve are affected, the inference

is that the cause of paralysis is acting upon the common trunk of the nerve; and such a cause is not infrequently the presence of periosteal swelling at the sphenoidal fissure. If only some of the muscles are affected, the inference is that the cause of the paralysis is either limited to the central nuclei of origin of certain filaments, or else that it is situated anteriorly to the division of the main trunk into the branches which proceed to different parts; and it is conceivable that the limitations of the paralysis may point, with tolerable certainty, to the precise locality of the disorder.

The causes of ptosis, as of other paralytic affections of single cranial nerves, apart from injuries and the pressure of morbid growths, may almost be reduced to syphilis and to impaired nutrition of the centres, the latter usually connected with hard mental work and worry. In every case, evidence of syphilis should be carefully sought for; and, if found, should determine the nature of the treatment, as it will also of the prognosis, which, in such instances, may be generally favourable. In cases of the second class, where there is no evidence of syphilis, and where the symptoms point to general impairment of nervous energy, the administration of iodide of potassium, in combination with tonics, will sometimes be useful; but the

main reliance must be placed upon rest, good living, and external surroundings favourable to the restoration of health.

5. *Diplopia*.—Double vision, although it has no proper relation to the subjects treated of in the present section, is yet so far allied to ptosis that, when occurring suddenly, it is almost always an effect of paralysis or of paresis either of the sixth nerve of one eye, supplying its external rectus, or of the branch of the third which supplies its internal rectus. In the former case the affected eye will deviate inwards, and will have limited range of movement towards the outer canthus; while in the latter case these conditions will be reversed.

As regards the causes and treatment of these limited forms of paralysis, there is nothing to add to what has already been stated about ptosis. It is sometimes desirable, while the diplopia continues, to exclude the deviating eye from vision by a shade, an opaque spectacle-glass, or other suitable contrivance, on account of the vertigo and uncertainty of gait which may be occasioned by the double images.

**FACHINGEN**, in Nassau, Prussia. Acidulous gaseous waters.—See MINERAL WATERS.

**FACIAL PARALYSIS**.—SYNON.: Paralysis of the Portio dura; Bell's Paralysis.

**DEFINITION**.—Paralysis of the muscles of the face, due to disease or injury of the nucleus or fibres of the seventh nerve (the portio dura of the seventh pair, according to the older nomenclature).

Above the nucleus, the motor path for the face decussates, and joins that from the arm and leg; damage, therefore, in the pons (above the crossing), in the crus, internal capsule, or hemispheres, may produce facial paralysis, but does so usually as a part of hemiplegia. This paralysis, which is on the same side as that in the limbs, is partial only, affecting chiefly the muscles of especial unilateral use (as the zygomatici); and very little those of solely bilateral use, in the upper part of the face—*e.g.* the frontales. In this article paralysis from damage to the fibres or nucleus of the nerve itself will alone be considered.

**ÆTIOLOGY**.—(1) The most common causes of facial palsy are unilateral, and damage the nerve as it passes through the narrow canal in the temporal bone. There, the slightest inflammatory effusion will cause pressure on the nerve. Such neuritis may be due to exposure to cold (and is often then called 'rheumatic'); to contiguous bone-disease, as caries; and sometimes to syphilis. Hæmorrhage into the sheath may also compress the nerve. Cold is the most common cause of palsy, but the exposure is often forgotten; it has been supposed to act by paralysing the peripheral nerve-twigs, but this is never the case in one-sided paralysis; in all cases lasting more than a few days, evidence of changed nutrition may be detected in the nerve-trunk as it emerges from the stylomastoid foramen. External cellulitis may extend into the canal. Tumours of the bone and fracture of the base may also damage the nerve as it passes through the bone. (2) Injury to the nerve outside the skull by blows, pressure by forceps in instrumental delivery, incised wounds—accidental or surgical, or parotid and other tumours, are occasional causes. (3) Within the skull the nerve may be dam-

aged by meningitis, acute or chronic, and especially by syphilitic inflammation, or by pressure of neighbouring growths. The radi- cular fibres within the pons, or the nucleus beneath the fourth ventricle, may be damaged by hæmorrhage, softening, or by tumours involving that part.

*Double facial paralysis* is very rare, and is due to damage to both nerves at the base of the brain from meningitis or symme- trical syphilitic disease; to symmetrical otitis; or to an affection of the nuclei by disease of the pons, or to loss of function of the nerve-fibres in various forms of peri- pheral neuritis. It is probably by the latter agency that double facial paralysis some- times results from toxic blood states. Syphilis and diphtheria are the most common ante- cedents of double facial palsy not due to demonstrable injury to the nerves. Disease of the nuclei affects both sides most fre- quently when it is degenerative in nature; it is then commonly partial, involving espe- cially the lip muscles in labio-glossal para- lysis, or the orbicularis palpebrarum in rare cases of nuclear ophthalmoplegia. Lastly, it may be mentioned that the facial muscles (generally those in and about the lips—rarely all) are occasionally involved in idiopathic muscular atrophy, and an affection of the nerves may be thus simulated.

**SYMPTOMS.**—The onset of facial paralysis is usually rapid, when due to its common causes, including neuritis within the canal. It occupies from a few hours to three or four days in its development. It is found, for instance, one morning, in drinking, that the fluids run out of the side of the mouth; the face is noticed to be a little unsymmetrical; at night the eye cannot be completely closed, and next morning the paralysis is found to be complete. Rarely the onset is in a few minutes; probably then a hæmorrhage into the nerve-sheath is the cause. When infla- mation is excited by cold, the symptoms often commence within twenty-four hours of the exposure. They are usually preceded or accompanied by some pain about the ear or side of the head.

In complete unilateral facial paralysis all the muscles on one side of the face are paralysed. At rest, the smooth forehead and lowered angle of the mouth are the chief indications, but on movement the difference between the two sides becomes very marked; the one half of the forehead moves alone in frowning or elevation of the eyebrow. The eyelids cannot be brought together, and in the attempt to close the eye, the globe is rolled upwards, so that only the sclerotic appears between the gaping lids; the patient then often fancies that the eye is shut. During sleep the eye remains open. In smiling, the lips may be displaced altogether to the healthy side, from the unopposed action of the zygomatic muscles; the nostril

of the affected side cannot be dilated; the upper lip cannot be raised; the cheek flaps loosely, from the relaxation of the buccinator; and, from the same cause, food accumulates between the jaws and the cheek. Whistling is impossible, from the paralysis of half of the orbicularis, and the lips cannot be ap- proximated sufficiently even to permit of a candle being blown out. When the lesion is between the junction with the large petrosal and that with the chorda tympani nerves, taste is partly or entirely lost in the front of the tongue. The loss of power of recognising acid and saline substances is most marked; but bitters and sweets are also not tasted in this part. Such loss is common in neuritis from cold, and shows that the inflammation has extended some distance up the canal. In rare instances, loss of taste has followed division of the nerve outside the skull, prob- ably always because secondary inflamma- tion has passed up the nerve. The palate is never paralysed from disease of the facial nerve. It is certain that the opposite statement rests on defective observation or interpretation. Obliquity of the uvula is common under normal conditions. Defect of movement, to be significant, must follow the course of any associated palsy of external muscles. The nerve-supply of the palatine muscles has been proved to be from the spinal accessory.

In some cases giddiness attends the onset of facial paralysis. In slight forms there may not be complete loss of power; but the defect is at first pretty equally distributed over all parts of the face.

In cases which recover, some return of power takes place in from a week to two months, and improvement is usually earliest in the upper part of the face; the power of frowning, winking, and closing the eye being soonest regained; that of moving the lips and mouth returning last. Even after several months of immobility, recovery may take place, but in these cases it is rarely complete, and a troublesome condition is apt to super- vene: some of the muscles, especially the zygomatici, become shortened in late rigidity, and hence at rest the naso-labial wrinkle is deeper on the paralysed than on the healthy side, although the possible movement may be much slighter. This condition sometimes comes on rather rapidly; there is generally, in addition, an associated over-action of the upper and lower facial muscles, whereby, for instance, the orbicularis palpebrarum and the zygomatic and other muscles about the mouth act together in undue degree; in smiling, the eye shuts; and on closing the eye, the mouth is drawn upwards. Sometimes there are also spontaneous clonic contractions. This late rigidity and over- action may prove very troublesome and con- stitute a nuisance, especially to the young, not less than the original palsy, and more

serious in that it is enduring. The writer has known it induce a good-looking girl to put an end to her life. If the interruption of the nerve is absolute and permanent, the muscles remain toneless, and no contracture supervenes.

The electrical condition of the muscles is very important. It is that always seen in paralysis from nerve-lesion. The muscles, after a day or two of slightly increased irritability to both faradism and the slowly interrupted voltaic current, lose gradually their irritability to the former, retaining that to the latter, and even exhibiting to it increased irritability, so that they act to a smaller number of cells than do those on the healthy side. In the nerve, on the other hand, the irritability is lost to both forms of electricity, this loss proceeding *pari passu* with the degeneration which follows separation of the nerve from its nutrient centre. In slighter and more transient forms of facial paralysis, the change in irritability of muscle and nerve may be less; but even in most, which last only a few days, a slight change in irritability may be discovered. In the slightest cases (and in the earliest stage of more severe forms) there may be an increased irritability in the nerve, often most marked to the induced (faradic) 'shocks'—*i.e.* isolated currents. Considerable change in irritability is proof of considerable disease of the nerve, and is thus of the highest prognostic importance, but it is not distinct until after a week; if absent at the end of a fortnight, the disease is slight, and although the paralysis may still be complete, it will probably not last long.

**DIAGNOSIS.**—The diagnosis of facial paralysis (commonly so-called—*i.e.* that due to disease of the nerve or its nucleus) is easy. It depends (1) on the implication of all the facial muscles, including those of bilateral use that escape in hemiplegia, because related to both cerebral hemispheres; (2) on the indication afforded by the electrical reactions that the nerve or its nucleus is diseased. Hence it is important to observe all the muscles of the face, and to ascertain the electrical reaction, in order to determine whether it is the variety now described, or is cerebral and really part of hemiplegia. The recognition of the place of the lesion is less easy. When within the pons, it is often associated with paralysis of the sixth nerve, or with hemiplegia of the opposite side from damage to the motor path to the limbs. At the base of the brain the auditory nerve is usually affected at the same time, but care must be taken not to mistake deafness due to ear-disease for an affection of the auditory nerve within the skull. When there are no other paralyses, the disease is probably within the bony canal. Deviation of the uvula is of no significance; affection of taste in the front of the tongue indicates disease within the canal. Special inquiry should be made

for exposure to cold, ear-disease, syphilis, or a blow.

**PROGNOSIS.**—The majority of cases of facial paralysis are due to disease of the nerve, and the prognosis depends on the evidence of the degree of damage to the fibres, especially on the indications afforded by an electrical examination, and also on the cause of the lesion. When this is progressive in nature, the interference with the nerve is necessarily persistent in duration. Thus, in facial paralysis due to a growth damaging the nerve, the prognosis must be grave. In syphilitic disease, on the other hand, it is good, provided the duration of the damage to the nerve is short. This is also the case in paralysis from cold, in which, however, the evidence afforded by electricity is of special importance.

In double facial paralysis, the evidence of central mischief renders the prognosis unfavourable, but recovery may be hoped for if the lesion is acute and the palsy incomplete. In syphilitic cases, the prognosis is, on the whole, good. In all cases of double facial palsy from peripheral neuritis, there is a similar affection of other parts, and the prognosis must be determined by the general character and course of the affection, and especially the degree to which the morbid blood-state is amenable to treatment.

**TREATMENT.**—The treatment of facial paralysis will depend on the probable cause. When due to its common mechanism—neuritis from cold, hot fomentations to the side of the head and face should be employed in the early stage of the affection, followed by a blister behind the ear. A blister should never be applied in front of the ear, over the opening of the canal, because it will cause some subcutaneous cellulitis, and such cellulitis may actually cause facial neuritis by spreading to the nerve-sheath in the canal. The side of the head should be protected from cold. Internal treatment of neuritis must vary according to the cause. If this is syphilis, iodide of potassium in 10 gr. doses may be given; if exposure to cold, diuretics and small doses of mercury in the early stage, followed by tonics. Electricity to the muscles is needed if the damage to the nerve is so severe as to entail secondary degeneration and consequent changes in nutrition. If there is no change in irritability at the end of a fortnight, recovery will probably occur so soon as to make electrical treatment superfluous. If needed, the voltaic current should be used, slowly interrupted by a commutator, or by the positive or negative pole being moved over the individual muscles (according as they react more readily to the one or the other), the opposite pole being placed over the nerve. Only such strength should be employed as produces distinct muscular contraction. Although electricity probably does no more, it keeps up the

nutrition of the muscular fibres while the nerve is recovering. Ultimate recovery is thus more speedy and more complete than without local treatment. The application can be made quite well by the patient, one electrode being kept over the place where the nerve divides, the other moved (1) across the forehead; (2) along the eyebrow; (3) along the lowered upper eyelid; (4) along the raised lower eyelid; (5) beside the nose to the upper lip; (6) along the upper lip; (7) along the lower lip; (8) from the zygoma to the angle of the mouth. In (3) and (4) the current should be weaker than in the other places. Rubbing may be employed, the individual muscles being subjected to a process of gentle shampooing. The late contraction which occurs in severe cases is but little influenced by treatment. Gentle elongation of the muscles may be practised, and electrical applications should be stopped, since the stimulation of the sensory nerves may increase the late contraction by a reflex influence; its occurrence shows that a point has been reached when the influence of electricity for good can be but small.

In external mischief, and in intracranial disease, the treatment of the facial paralysis is usually subordinate to that of its cause.

The treatment of double facial paralysis presents no special points for consideration, except when it is part of multiple neuritis, the indications for which are described in a special article. W. R. GOWERS.

**FACIAL SPASM.**—**SYNON.**: Mimic cramp; Fr. *Tic convulsif*. When affecting the eyelids, Blepharospasm; Nictitation.

**DEFINITION.**—Spasm, sometimes tonic but more often clonic, or both, involving some or all of the muscles supplied by the facial nerve, on one side or on both.

**ÆTIOLOGY AND SYMPTOMS.**—Spasm in the face may be part of a wider convulsive movement, as in epilepsy, hysteria, chorea, or torticollis, diseases dependent on central changes. That which begins in, and is limited to one side of the face, may be due to irritation of the trunk of the facial nerve by growths, by an aneurysm, or caries of the temporal bone, or to an actual lesion of the motor centre for the face in the cortex of the brain. Spasm due to disease of the nerve may follow facial paralysis (*see* FACIAL PARALYSIS). Much more frequent, however, are cases, unilateral or bilateral, in which the affection comes on gradually, chiefly in females in the second half of life, after depressing emotion. It is probable that such cases are due to deranged functional action of the cortical motor cells, through which, we may remember, emotion is so extensively expressed. In such cases the affection usually begins on one side, often in the orbicularis palpebrarum; and if it spreads to the other side, this muscle is first involved. In another group of cases, affec-

tions of the eye lead to spasmodic closure of the lids—*blepharospasm*. In other cases beginning in the eyelids, no local cause can be detected, as in the local clonic spasm affecting the orbicularis palpebrarum, known as ‘involuntary winking’ or *nictitation*, which seems to be a pathological development of the normal process. This is also a common seat of the spasm in the face that is part of ‘habit-spasm’ or ‘habit-chorea,’ but it has no connexion with true chorea.

Facial spasm is painless. The spasm is usually increased by emotion, by voluntary movement, and by stimulation of the fifth nerve. Slight aural symptoms have been observed, referable to contraction of the stapedius. Usually the movement remains limited to the face; sometimes it spreads to the muscles of mastication, of the neck, &c. The spasm, in typical cases, is both tonic and clonic, clonic paroxysms occurring from time to time, and being fixed by tonic contractions, or *vice versa*. All forms cease during sleep.

The only secondary form of facial spasm (besides that which supervenes on a paralysis of the nerve) is the clonic spasm in the frontales that is often met with in the form of ‘torticollis’ to which the writer has given the name of ‘retrocollic spasm.’ In this there are bilateral contractions in the muscles of the back of the neck, jerking the head backwards. These muscles are physiologically associated with the frontales, as may be seen when a person looks up, and this association is reproduced in disease.

**PROGNOSIS.**—The prognosis of facial spasm is seldom good. If the cause can be discovered, it can rarely be removed, and the affection is generally most obstinate.

**TREATMENT.**—General tonics and local sedatives are the chief agents in the treatment of most forms of facial spasm. When there is evidence of direct irritation of the fifth or the facial nerve, counter-irritation by blisters may be tried. A careful search should be made for reflex causes, and if possible they should be removed, decayed teeth being extracted, and neuralgia relieved, although the result is generally disappointing, if the spasm has long existed. When there are tender places in the course of the fifth nerve, pressure on which stops the spasm, the hypodermic injection of cocaine at these places should be employed. Morphine, used as a sedative, has a general influence which makes the remedy almost worse than the disease. Iron, quinine, or valerianate of zinc are the best general tonics. The writer has once known recovery to follow the administration of bromide, Indian hemp, and nuxvomica; the case was characteristic, occurring late in life. The operation of nerve-stretching has often arrested the spasm for a time, and, in a few cases, permanently. It deserves a trial in severe cases, acting, perhaps, by the effect on the centres of the arrest of

afferent impulses produced by the muscular contractions. These must tend to maintain the morbid state of the deranged cells. Its effect might probably be augmented by the simultaneous use of sedatives, such as the injection of cocaine to lessen the influence of the fifth nerve on the facial centre. Where the affection springs from an habitual movement, facial gymnastics may be of service. A weak voltaic current, applied from the ear to the muscles, unbroken, has been recommended; but it rarely, if ever, effects a cure. The same is true of the application of voltaism to the sympathetic and to the back of the head. *See EYE, AND ITS APPENDAGES, Diseases of.* W. R. GOWERS.

**FACIES HIPPOCRATICA** (Lat.)—A peculiar expression of the face, so named from having been graphically described by Hippocrates. It is most strikingly observed in persons exhausted by copious discharges, as in cholera, by prolonged wasting diseases, or by starvation; and especially before impending death. It is thus described by Hippocrates: 'A sharp nose, hollow eyes, collapsed temples; the ears cold, contracted, and their lobes turned out; the skin about the forehead being rough, distended, and parched; the colour of the whole face being green, black, livid, or lead-coloured.'

**FÆCES, Examination of.**—*See STOOLS.*

**FÆCES, Involuntary Discharge of.**  
*See DEFÆCATION, INVOLUNTARY.*

**FÆCES, Retention of.**—**ÆTIOLOGY.**—In the absence of mechanical obstruction, such as that due to adhesions, bands of false membrane, uterine pressure, stricture, tumours or hæmorrhoids, the main causes of fecal accumulation are:—(a) A sub-paralysis of the intestinal muscular fibres from defective innervation, or from over-distension of the walls of some portion of the large bowel; (b) loss of reflex irritability of the rectum; and (c) dryness of the mucous surface of the colon. Hence it is frequently met with in the debilitated, the bedridden, the paralysed, the aged, and the sedentary; and women are more prone to it than men. Loss of reflex sensibility in the rectum is frequently the sole cause. The fæces delivered into the rectum by the contractions of the sigmoid flexure and the descending colon no longer excite the act of defæcation; and collecting there as a large desiccated mass, they determine a gradual and painless retention in the large intestine, and particularly in the most distensible parts—the sigmoid flexure and the cæcum. The accumulation once set up tends also to perpetuate itself, by arresting more and more the peristaltic movements of the distended bowel around the collected fæces.

**SYMPTOMS.**—Fæces often accumulates slowly and without the knowledge of the patient. Hence in cases in which sensibility has been

blunted by age, disease, or great debility, the discovery of large collections in the rectum or colon may surprise even the practitioner, who is generally led to a local examination by disturbances set up by the retention. There is usually constipation or an insufficient discharge of solids; a regular and possibly excessive relief of the bowels does not, however, exclude accumulation, for even fluid fæces may pass through or over old collections. The evacuations are lumpy, or consist of detached hard, dry, dark scybala, or of a single mass; and when the accumulated matters are dislodged by aperients, they often emit an offensive and sour odour. Not uncommonly, however, the alvine discharges are entirely fluid or semifluid, and consist chiefly of mucus tinged with fæces. Fæcal collections in the rectum and sigmoid flexure are apt to excite tenesmus and frequent voiding of mucus and blood—a condition resembling that of chronic dysentery, but without the putrid-flesh-like odour of dysenteric evacuations; and the finger encounters a mass of hardened fæces in the rectum. A collection of fruit-seeds—as of the fig—in the rectal pouch will also set up these symptoms.

An accumulation in the cæcum, or in any part of the colon, may be detected through the abdominal wall as a tumour more or less movable, uneven or nodulated, and doughy to the touch; and on the finger being firmly pressed into it, presenting a depression which may last for some minutes. In rare cases the large bowel throughout may be so greatly distended as to apparently fill the abdomen with a solid mass, which, like other fecal collections, yields to the firm pressure of the finger. A tympanitic state of the abdomen may, however, so obscure the examination as to prevent the recognition of even moderately large accumulations. The fecal tumour in the cæcum is globular; but in any part of the colon it is usually elongated; and in the descending colon and sigmoid flexure it is harder than elsewhere, and very distinctly nodular from scybala. It may drag the transverse colon downwards, even as low as the symphysis pubis; and when confined to the right half of the transverse colon it may be mistaken for an enlarged liver.

But in other cases the retained fæces set up more or less severe abdominal disturbance—such as colicky pains, great distension, &c.—which may terminate either gradually or suddenly in complete intestinal obstruction, now and then proving fatal (*see* **INTESTINAL OBSTRUCTION**). Usually, however, several obstructive attacks of increasing severity succeed one another at intervals, being relieved either spontaneously or by the use of enemata and aperients. Ulceration of the intestinal mucous membrane is also apt to follow the continued retention of fæces, and may lead to fatal perforative peritonitis, or to stricture from the healing of the stercoral

ulcer. See CÆCUM, Diseases of; COLON, Diseases of; and CONSTIPATION.

**TREATMENT.**—A hard ball of fæces, or of agglutinated scybala, or fæcal concretions in the rectum resisting dislodgment by aperients or enemata, should be broken up and removed by introducing within the sphincter two or three fingers and a scoop, or the handle of a spoon; this procedure in the female being facilitated by the fingers in the vagina. An attempt may be made as a preliminary measure to macerate the hard fæcal mass by a cacao-butter suppository or injecting a few ounces of warm olive-oil. Sometimes a glycerine suppository or glycerine injection (5ij.) will excite and aid the natural efforts in expelling the obstruction. Symptoms of obstruction should be met by injecting by the stomach-pump tube, or Davidson's syringe, large quantities—from 80 to 120 oz.—of some warm fluid such as soap-water or gruel, through the long rectal tube passed its full length; and it is often advisable to repeat at intervals the injection of even large quantities until relief is obtained. Care must be exercised in the use of the long tube not to injure the bowel; as well as in the injection of large quantities of fluid. If the indurated mass (as when in the lower parts of the large bowel) can be traversed by the tube, warm olive-oil should be slowly injected, and afterward the warm fluids in ample measure. As a rule, purgatives merely aggravate the vomiting induced by the obstruction, while large enemata usually afford direct relief. In the absence of vomiting, however, a brisk aperient—such as calomel, castor-oil, or colocynth with croton-oil—may afford timely aid in clearing away the fæcal accumulation. When aperients and enemata fail to dislodge the fæcal collections, and the abdomen becomes painfully distended, a combination of opium, belladonna, and aloes, given at regular intervals—the dose of aloes, at first small, being increased as the pain diminishes—may enable the bowel to overcome the difficulty; but when there is much pain, and, above all, obstinate and especially stercoraceous vomiting, opium and belladonna, or subcutaneous injection of morphine, should be given until the subsidence of these symptoms. In such cases belladonna alone pushed to large doses has been known to effect relief after the failure of other means.

Massage may afford aid in dispersing fæcal collections and improving the peristaltic action of the bowel; to be applicable, there should be little or no tenderness, and it should be addressed first of all to the distal side of any detectable fæcal tumour. Electricity may prove useful. See CONSTIPATION.

Distressing tympanites, which, thwarting the peristaltic movements, often intensifies obstruction, has been overcome by puncturing the bowel with a fine trocar or aspirator-needle, after failure of other measures.

The general medicinal treatment of the conditions that favour the recurrence of the difficulty should consist of a prolonged course of gentle, yet efficient, evacuants, combined with tonics. The gradual collection of fæces, the toneless state of the walls of the large bowel, the scanty secretion of intestinal mucus, and the loss, in many cases, of reflex sensibility in the rectum, require the persevering use of these remedies. A pill containing aloes, iron, belladonna, and nuxvomica generally affords the most satisfactory results. See CONSTIPATION.

GEORGE OLIVER.

**FAINTING.**—A popular synonym for syncope. See SYNCOPE.

**FAINTNESS.**—Faintness signifies a feeling of great weakness or exhaustion, as if the subject of it were about to become exhausted, or to sink or faint.

**FALLING SICKNESS.**—A popular synonym for epilepsy. See EPILEPSY.

**FALLOPIAN TUBES, Diseases of.** The oviducts are liable to the following morbid conditions:—(1) Malformations; (2) Displacements; (3) Contractions; (4) Dilatations; (5) Inflammation; (6) New-Growths; and (7) Tubal Pregnancy.

1. **Malformations.**—The Fallopian tubes may be congenitally wanting, either on one or on both sides; or they may be impervious; or, instead of a single opening into the abdominal cavity, there may be two or more.

2. **Displacements.**—The tubes may be stretched or widely displaced from their normal position by growths or effusions in their neighbourhood, such as ovarian, or parovarian.

3. **Contractions.**—These canals may be impervious, from inflammation of the lining membrane, or from peritonitis, pressure, or torsion.

4. **Dilatations.**—The Fallopian tubes may be distended, even to a great extent, by (a) mucous or serous fluid (*hydro-salpinx*); (b) pus (*pyo-salpinx*); or (c) blood (*hæmo-salpinx*). In hydro-salpinx the tubes, if much distended, become sacculated, giving rise to a string of cystic tumours. The fluid collects chiefly at the abdominal end of the tube, but occasionally it may escape, and in large quantity, through the uterus. Should the tube burst and discharge its contents into the peritoneal cavity, the results will be serious, especially if the fluid be pus. When hæmo-salpinx is the result of menstrual retention from atresia uteri, bursting of the tubes internally is liable to follow operations for the relief of the obstruction.

5. **Inflammation.**—Inflammation of the Fallopian tubes (*salpingitis*) is apt to be caused by gonorrhœal infection, or it may occur during the puerperal state. Stenosis or *pyo-salpinx* may be the result.

6. **New-Growths.**—The Fallopian tubes may be the seat of the following new-growths: fibroid tumours, mucous polypi, cysts, cancer, and tubercle. Fibroids resembling those of the uterus may attain a considerable size. Small polypi growing into the canal may partially obstruct the duct. The cysts are usually the so-called *hydatis of Morgagni*, an embryological relic; but other small simple cysts may be met with at the orifice of the tube, around the fimbriated extremity. Primary cancer of the Fallopian tubes rarely, if ever, occurs. Tubercle, however, may be primary, and may occur before puberty. It usually begins at the abdominal end, and may lead to blocking of the tube.

7. **Tubal Pregnancy.**—An important affection of the Fallopian tubes is that arising from disintegration of the lining membrane of the tube, producing destruction of the ciliated epithelium, and so affording a nidus for the attachment of the misplaced product of conception, which thus grows within the tube in some part of its course. This abnormality is apt to be attended with very grave results, bursting of the tube frequently occurring about the third month of gestation; and serious, sometimes fatal, internal hæmorrhage may hence ensue. Tubal gestation usually occurs on one side only, while other affections of the tubes are often symmetrical, a point of diagnostic importance. See PREGNANCY, Disorders of.

**Regurgitation** of blood, of septic matters, and of fluids injected into the uterus, sometimes takes place along the Fallopian tubes, and this accident is always attended by grave consequences. Hence the danger of injudicious intra-uterine irrigation with corrosive sublimate and other antiseptic solutions during the puerperal period, and more especially after early abortions.

**Mechanical Obstruction** of the Fallopian tubes is not an infrequent cause of sterility.

**TREATMENT.**—The diagnosis of affections of the Fallopian tubes being difficult, their treatment is likewise obscure, and must be in a measure guided by general principles in each case. In pyo-salpinx severe peritonitis and death may result from rupture of the sac, as may speedy dissolution from internal hæmorrhage in tubal gestation. In the former case, and in hydro-salpinx, puncture with the aspirator might be permissible were a clear and unequivocal diagnosis made; or, failing this, the removal of the affected tube by salpingotomy as the only alternative. But, although in the hands of some eminent specialists this procedure has been attended with satisfactory results in many cases within the past few years, as a rule, under ordinary circumstances, the diagnosis is surrounded by so many difficulties that such an operation can only rarely be justified.

ALFRED WILTSHIRE. T. MORE MADDEN.

**FALSE MEMBRANE.**—An inflammatory exudation of a fibrinous character, which is deposited in layers, chiefly on mucous surfaces, and occasionally on abrasions of the skin. It is well exemplified in diphtheria and plastic bronchitis. See DIPHTHERIA.

**FAMILY DISEASES.**—Diseases which are found to run in families, or diseases to which members of the same family seem peculiarly liable. See DISEASE, Causes of.

**FARADISATION, Uses of.**—See ELECTRICITY IN MEDICINE.

**FARCY.**—See GLANDERS.

**FASCIÆ** (*fascia*, a band).—The fasciæ are subjects of medical and surgical interest, with respect to their anatomical relations, the diseases to which they are liable, and certain points of diagnosis in connexion with them.

**I. Anatomical Relations of Fasciæ.**—The situation and connexions of the fasciæ, according as they are fasciæ of *investment* or fasciæ of *attachment*, are of the greatest practical importance in the following classes of diseases: (1) Suppuration; (2) Extravasations, and Cellular Emphysema; (3) Herniæ; (4) Dislocations and other injuries; (5) Diseases of Encapsuled Organs; and (6) New-Growths.

**1. SUPPURATION.**—The physical influences exerted by fasciæ upon pus are chiefly two. First, fasciæ may limit the size of an abscess, determine its tension and the many results of the same, and thus affect both the local phenomena and the general symptoms. Secondly, when the pus is not confined, the fasciæ serve to determine the course that it will take, and the situation in which it will discharge. Every abscess may be said to be influenced in this way by the relations of fasciæ, but certain fasciæ have to be specially noted as causing pus to burrow, and hence they should be enumerated here.

(a) *Fasciæ of the Head and Neck.*—The fasciæ of the scalp; the temporal fascia; the cervical fascia; and the post-pharyngeal fascia, which conducts pus from the cervical vertebræ to the parotid region and tonsil, and to the region of the carotid vessels.

(b) *Fasciæ of the Upper Extremity.*—The axillary fascia; and the deep fascia of the upper extremity generally, including the palmar fascia and the sheaths of the tendons.

(c) *Fasciæ of the Thorax.*—The fasciæ of the intercostal spaces and of the mammary region; the fasciæ reaching from the neck to the upper part of the pericardium and the aorta, and to the posterior mediastinum, respectively; the fasciæ of the anterior mediastinum; and those connected with the diaphragm—all of which determine the course of intrathoracic abscesses

(d) *Fasciæ of the Abdomen and Pelvis.*—The transversalis fascia; the fasciæ connected with the transversalis muscle, especially posteriorly, which influence the course of lumbar abscess; the sheaths of the psoas and the iliacus muscles; the pelvic, recto-vesical, obturator, and anal fasciæ; the fascial investment of the prostate; the superficial and deep layers of the superficial fascia of the perinæum; the superficial and deep layers of the triangular ligament; and the fascial investments of the rectum, bladder, uterus, and vagina, which determine the course of purulent collections in the pelvis.

(e) *Fasciæ of the Lower Extremity.*—The fascia lata and its processes; the tensor fasciæ femoris; the popliteal fascia; the deep fascia of the leg; and the plantar fascia and its compartments.

2. EXTRAVASATIONS AND CELLULAR EMPHYSEMA.—When blood or urine escapes from its natural reservoirs, or when air or gas has found its way amongst the tissues, the direction that the extravasated substance takes is markedly influenced by the fasciæ with which it comes in contact. The principal fasciæ of importance in this respect are as follows:—

(a) *Fasciæ of the Head and Neck.*—The fascia of the scalp, and the cervical fascia.

(b) *Fasciæ of the Thorax.*—The fasciæ of the intercostal spaces; and the mediastinal fasciæ, through connexions with the cervical.

(c) *Fasciæ of the Upper Extremity.*—The deep fascia in general.

(d) *Fasciæ of the Abdomen and Pelvis.*—Scarpa's fascia, or deep layer of the superficial fascia; both layers of the superficial and of the deep perineal fascia; and the fasciæ of the prostate and bladder—all being of the greatest importance in cases of extravasation of urine or feces.

(e) *Fasciæ of the Lower Extremity.*—The fascia lata in general; the popliteal fascia; the deep fascia of the leg; and the plantar fascia.

3. HERNIÆ.—The occurrence of herniæ, and the direction that they take, are in a great measure determined by the condition of the fasciæ in contact with the viscera. Most important in this relation may be mentioned the fascia transversalis, the iliac fascia, the sheath of the femoral vessels, the obturator fascia, the cribriform fascia, and the fascia lata.

4. DISLOCATIONS, &c.—Certain fasciæ serve as supports for the heads of bones, and for the viscera; and these will have an important influence either in promoting or in preventing dislocation, displacement, or other injury of these parts, as the case may be. The shoulder is supported by the costo-coracoid fascia, and this relation considerably affects the signs of dislocation at that joint. In fractures of the patella, the fasciæ of the knee-joint promote separation of the frag-

ments. The fascia of the neck helps to support the pericardium, and must limit the displacements of the heart. The bicipital fascia of the forearm protects the brachial artery beneath it in venesection, at the bend of the elbow. On the other hand, the attachment of the cervical fascia to the jugular veins facilitates the entrance of air into the circulation through a wound at this point. And, lastly, the pelvic viscera are supported by the transversalis, pelvic, iliac, and recto-vesical fasciæ; whilst the cord and testis have their special fasciæ to keep them in position.

5. DISEASES OF ENCAPSULED ORGANS.—A considerable number of organs, many important vessels, and a great variety of muscles are contained in distinct fascial capsules, sheaths, or envelopes, which will affect the course of the diseases of these structures in many ways—defining their limits, or determining the direction in which they spread, and thus influencing both their local and general phenomena. This has been already alluded to under the first head; but it is necessary to enumerate here the principal fasciæ that act in this way, namely:

(a) *Arterial sheaths:* of the carotid, subclavian, thoracic-aortic, and femoral. (b) *Muscular sheaths:* of the masseter, buccinator, psoas, iliacus, quadratus lumborum, erector spinæ, pectineus, rectus abdominis, levator ani, tensor vaginæ femoris, and the palmar and plantar muscles. (c) *Visceral capsules:* of the thyroid gland, parotid and submaxillary glands, tongue, prostate, penis, vagina, bladder, rectum, and mamma.

6. NEW-GROWTHS.—The direction, rapidity, and extent of spread of new-growths are considerably modified in certain situations by the relations of the fasciæ above described.

II. Pathological Relations of Fasciæ.—The principal diseases of fasciæ are: (1) Inflammation and its results; (2) Ossification; (3) Calcification; (4) Rheumatism; (5) Gout; (6) Syphilis; (7) Contraction; and (8) Extension. None of these conditions can be said to be common, or of serious importance.

1. INFLAMMATION.—Inflammation involving a fascia is usually secondary, having spread to it from the neighbouring structures, and especially from the muscle or organ of which the fascia may form the sheath. Even under these circumstances, a fascia rather resists than participates in the inflammatory process, as has been described above; and when it is involved, it tends to ulcerate on account of its feeble vitality, and to be discharged in the form of sloughs. The healing process is extremely slow in fasciæ, and after serious lesion their function is never completely restored.

2. OSSIFICATION.—Occasionally in aged persons portions of fasciæ are found transformed into bony tissue.

3. **CALCIFICATION.**—Calcification is very rare in fasciæ.

4. **RHEUMATISM.**—The condition known as muscular rheumatism, or according to its situation as lumbago, torticollis, &c., is believed by some authorities to involve the fibrous coverings or fasciæ of the affected parts. In the same way, many of the aches of some forms of 'chronic rheumatism' may possibly have their seat in fasciæ; and certain cases of neuralgia are probably to be referred to rheumatic inflammation of the nerve-sheath.

5. **GOUT.**—Amongst the pains of the gouty subject are some which are no doubt due to affections of fasciæ, such as pains in the heel and instep, and neuralgia of the sciatic, the anterior crural, and the brachial nerves.

6. **SYPHILIS.**—Syphilis may attack the fasciæ in the form of nodes, which in situations of low vascularity are apt to ulcerate, as, for example, at the inner aspect of the knee.

7. **CONTRACTION.**—Contraction is the most obvious of the morbid conditions of fasciæ, giving rise as it does to well-marked deformities. The fasciæ of the hand and foot are most liable to this change, with the result of unnatural flexion of the fingers and toes. Such contraction of the palmar and plantar fasciæ may be due to wounds, burns, or inflammation from any cause, or to gout or rheumatism; it is sometimes congenital; and it sometimes occurs without evident cause.

8. **EXTENSION.**—A fascia or sheath, though extremely inelastic, is liable to be stretched by swelling of the parts which it envelops; and, if the cause do not speedily disappear, may remain more or less permanently extended. The best instance of this condition is pendulous abdomen after pregnancy or other kind of abdominal enlargement.

J. MITCHELL BRUCE.

**FASCIOLA** (*fasciola*, a thin band).—A genus of trematode parasites of which the common liver-fluke forms a good type. This entozoon (*F. hepatica*) is characterised by the possession of a branched intestinal canal, thus differing from the flukes belonging to the genus *Distoma*, in which the canal is simple and bifurcated. The liver-fluke is of rare occurrence in man, though extremely abundant in, and destructive of, ruminating animals. See ENTOZOA.

T. S. COBBOLD.

**FASTING.**—The manifestation of vital activity implies consumption of material; and unless the supply of material in the form of food is equivalent to the loss occurring, a progressive wasting of the body and failure of power must ensue. Hence these phenomena constitute the necessary accompaniments of fasting; and with its prolongation the question resolves itself into one of time

—when the exhaustion of material shall have proceeded to such an extent as to render the continuance of life impossible.

**PATHOLOGY.**—To Chossat we are indebted for showing that the immediate cause of death from fasting is a reduction of the body temperature. At first there is a gradual, but not very extensive fall. Afterwards a more rapid decline occurs, until the reduction amounts to about 29° or 30° F. below the normal point, when death ensues. Chossat noticed that if, whilst in the state of torpor preceding death, the temperature of the animal experimented on was raised by exposure to artificial warmth, a restoration of consciousness and muscular power was induced; and some of his subjects of experiment which were thus rescued from impending death afterwards thoroughly revived on being supplied with food.

**SYMPTOMS.**—The most prominent symptoms arising from fasting are those due to the special sensations produced by the absence of food and fluid, and those attributable to a decline of the physical and mental powers. In the first place there is great uneasiness in the epigastrium. This is followed by a sense of sinking in the same region, accompanied by insatiable thirst; and if fluid be persistently withheld as well as food, the thirst becomes the chief source of distress. The countenance assumes a pale and cadaverous appearance, and a look of wildness is presented about the eyes. Emaciation becomes more and more marked, and with it there is a decline of the bodily strength. There is also failure of the mental power. Stupidity may advance to imbecility; and a state of maniacal delirium frequently supervenes. Life terminates either calmly by gradually increasing torpidity, or, it may be, suddenly in a convulsive paroxysm.

**DURATION OF LIFE.**—The usual duration of life under complete absence of food and drink may be said to be from eight to ten days. The special circumstances existing may, however, exert a modifying influence, and from the nature of these the period may be either diminished or increased. A stout person, as may be readily understood, has a chance of living longer than a thin one, on account of the store of combustible material which may be drawn upon being larger. Exposure to cold in conjunction with starvation very much hastens death. The presence of moisture in the atmosphere favours the prolongation of life, by diminishing the exhalation of fluid from the body. It may be assumed to be owing to the existence of warmth and moisture that persons buried in mines, or otherwise similarly placed, have been known to live considerably beyond the ordinary period.

The Welsh fasting girl, whose case caused so much sensational excitement in 1869, lived exactly eight days from the time she

was placed under systematic inspection to solve the problem of whether she could exist, as had been alleged by her parents, for an indefinite period without food. It appears that during the first part of the time she was cheerful and exhibited nothing extraordinary. Later on it was found that she could not be kept warm, and ultimately she sank into a state of torpor from which she could not be roused, and which speedily terminated in death.

In the Troedryhiw colliery near Pontypridd an inundation occurred in 1877, which led to the imprisonment of four men and a boy in one of the headings of the mine. The accident happened on Wednesday evening, the 11th of April. Efforts were at once made, by means of a cutting, to reach the chamber in which the imprisoned persons were confined, and to release them. This was not accomplished till the afternoon of Thursday, the 19th, when all were rescued alive and did well. They had been imprisoned in an atmosphere of compressed air nearly eight days, without food but within reach of water.

The performances of professional fasting men give a much longer time as that during which life can be sustained without food. Two feats of fasting were performed before the London public during 1890 by separate men. The first was announced to be for a period of forty, and the second for a period of forty-five days. Both were carried on for the specified time, and, through the payments received from the crowds of spectators admitted, must have proved lucrative undertakings. One of them subsequently became insane. Feats thus conducted for pecuniary gain, and supervised, as was here the case, by newspaper reporters as watchers, can hardly, it may be considered, be regarded as holding a sufficiently trustworthy position to command acceptance for the purposes of a medical work like this, whatever the amount of popular credence given to them at the time. In the case of the Welsh fasting girl watchings of considerable duration had been performed through which she had successfully passed, but the last watching was carried out by the experienced London nurses deputed to undertake the task with a strictness that defied deception, and with the result that death took place as stated.

In the case, again, of Ann Moore, of Tutbury, in Staffordshire, which, from the account published, must have attained great notoriety in the early part of the present century, watchings had been conducted in a manner to admit of testimony being given in support of her veracity; but ultimately a watching was so seriously undertaken, and with such zeal carried out, as to lead to her being brought by the ninth day into a sinking condition, when she took food, and afterwards made a written confession of the imposition that had been previously practised.

That a very small amount of food will suffice for sustaining life for a prolonged period is evidenced by what may be observed in some cases of constrictive disease affecting the œsophagus or cardiac orifice of the stomach.

**TREATMENT.**—Caution is required in the administration of food after prolonged fasting. Sudden transitions of all kinds are trying to the body; and, instead of allowing the rescued sufferer to gratify his desire to eat and drink according to his inclination after several days' abstinence, the supply of both food and drink should at first be limited, and afterwards gradually increased. There is reason to believe that the non-observance of this rule has upon some occasions been followed by disastrous consequences, which a different plan might have averted.

F. W. PAVY.

**FAT.**—Fat becomes morbid under a variety of circumstances:—

1. **Obesity.**—Fat may be found generally diffused in excessive quantity beneath the skin, beneath serous membranes, and in and upon various tissues and organs of the body. This condition constitutes what is known as obesity. See OBESITY.

2. **Partial Growth.**—A partial growth of fat sometimes occurs in paralysed muscles, and constitutes a characteristic feature of what is called pseudo-muscular hypertrophy. See PROGRESSIVE MUSCULAR DYSTROPHY.

3. **Fatty Interstitial Growths.**—Fat as fat-tissue more especially constitutes a disease when it is deposited upon and in the textures of organs, interfering with their structure and functions. This it does by pressing upon the histological elements of the organ invaded. Its effects are more clearly seen when it invades the muscular tissue of such an organ as the heart, the fibres of which, becoming more or less atrophied and distorted in their course and direction, are rendered inadequate for the performance of their functions. See HEART, Fatty Growth on.

4. **Fatty Tumours.**—Fat may also occur in isolated or circumscribed masses, constituting what are known as *fatty tumours* or *lipomata*. See TUMOURS.

5. **Fatty Infiltration.**—See FATTY INFILTRATION. RICHARD QUAIN.

**FATIGUE** (*fatigo*, *I weary*).—GENERAL REMARKS.—Fatigue is a regular and constantly returning symptom experienced by all persons. Periods of functional activity invariably alternate with periods of repose, during which the waste caused by the exercise of function is repaired. We are indebted to Sir James Paget for having pointed out that 'rhythmic nutrition is a law of nature,' and although the truth of this dogma is recognised on all hands, and may be said to be axiomatic, it has hardly

received that careful consideration at the hands of practical physicians which it deserves. Our whole life is composed of a series of vibrations—periods of tension alternating with periods of relaxation; and although the rapidity of these vibrations varies immensely, they are recognisable in all our acts, whether voluntary or otherwise. The vibrations of the heart are about seventy in a minute, those of the respiratory organs about sixteen. The whole body requires a certain period of absolute and continuous repose in each twenty-four hours (amounting to nearly one-third of the period), so that we may say its rate of vibration is once in the twenty-four hours. In like manner, the period of relaxation of the heart is about one-third of the total period of action, and this proportional correspondence between a local and a general condition is not a little interesting and suggestive. Again, it is universally ordained amongst civilised nations that once in every seven days there shall be a remission of labour and a change of occupation; and we recognise the fact that it is highly advisable for those who are occupied in one pursuit to break away from it at least once a year and indulge in that variety of work which we call amusement.

Fatigue occurs directly we attempt to alter the rhythm of our vital vibrations by prolonging the periods of tension at the expense of the period of relaxation, or by demanding for any length of time a quickening of the normal rate of vibration. We recognise the fact that athletes who over-train run risks of cardiac troubles and loss of wind; that the man who from any cause is unable to sleep runs a serious risk of permanent impairment of health; and when we find patients pursuing their avocations too zealously we know that, if such offence against the laws of nature be persisted in, general paralysis, or other forms of 'break-down,' are likely to be the result.

**DESCRIPTION.**—Fatigue may be either *general* or *local*, and both forms may be either acute or chronic. That fatigue in all its forms is due to impaired nutrition there can be little doubt, and we shall find that the symptoms of chronic fatigue are often the prelude of definite and recognisable degenerative changes.

**General Fatigue.**—General fatigue is recognised with ease both in its acute and chronic forms. There is a disability to perform either mental or physical work, and this disability is noticed first in work requiring attention or sustained effort, and last in those acts which have become automatic or secondarily automatic. The symptoms of general fatigue are usually referable to the nervous centres.

**Local Fatigue.**—Local fatigue is either acute or chronic, and the symptoms of it are referable usually to the muscles; but we

must always bear in mind that muscle and motor-nerve are practically one and indivisible, and that recent experiments have given great probability to the idea that every muscle is connected with a certain definite spot in the brain. When, therefore, we speak of a sense of fatigue, we must necessarily be in doubt, notwithstanding the fact that the symptoms are apparently located in the muscles, whether the brain, nerve, or muscle, one or all of them, be really at fault.

**Acute local fatigue.**—The first symptom of acute local fatigue is loss of power to a greater or less extent. By too frequent or too prolonged stimulation the irritability of the muscular tissue becomes exhausted, and it either refuses to respond, or responds but feebly to the stimulus of the will; whilst our power of adjusting the force of contraction to the act to be accomplished is lessened, and accuracy of movement and delicacy of co-ordination are destroyed. The second symptom is tremor, as everyone must have experienced who has been called upon for any unusual exertion. The third symptom is cramp-like contraction; and the fourth is pain, the pain being the pain of fatigue, and absolutely distinct from other varieties of pain. Fatigue is caused far sooner by prolonged muscular effort than by repetitions of short muscular efforts having due intervals of relaxation between them. Any one who has attempted to hold out a weight at arm's length knows the impossibility of continuing the effort for any length of time; and it is proverbially true that standing in one position is, to most people, far more tiring than walking, the reason being that in standing the muscles which support the body are subjected to a prolonged strain, while in walking we use the muscles on either side of the body alternately. The great increase of power which we obtain by using the muscles on either side of the body alternately would seem to be one of the chief reasons for the bilateral symmetry of the body. Not only is sustained effort a far more potent cause of fatigue than repeated effort, but we find that when fatigue supervenes, actions requiring sustained effort are the first to fail; and in this local fatigue resembles general fatigue. The last acts to be affected by fatigue are such as are automatic, and are accomplished without mental effort, and by the expenditure of the least possible amount of force. It is quite possible to exhaust a muscle by artificial stimulation, and if one of the small interossei muscles be continuously faradised, it will be found that in time its power of contraction to any form of stimulus may be absolutely abolished. It is tolerably certain that the brain can have no share in artificial fatigue thus produced, and there seems good reason to suppose that, in some people of energetic temperament, the irritability of a muscle may be exhausted, while

the power of mental stimulation remains almost unimpaired.

*Chronic local fatigue.*—This form of fatigue has causes and symptoms similar to those of acute local fatigue, and there can be little doubt that this condition is a common cause of many of those chronic maladies which seem to result from over-work, and are characterised by irregular muscular action. That some cases of writer's cramp (see WRITER'S CRAMP) are due to chronic fatigue of certain muscles employed in writing, and particularly of those subjected to prolonged effort, cannot be doubted. Some cases of torticollis seem due to the same cause. Duchenne and Brudenell-Carter have pointed out how, in cases of 'short sight,' the strain on the internal recti has caused troubles of vision, and even brain symptoms; and Mr. C. B. Taylor of Nottingham has shown reason for including in the category of fatigue-diseases a peculiar form of nystagmus, occurring amongst miners, who try their eyes by working in the dark. Dr. Augustus Waller, working at this subject from the physiological point of view, states that when a muscle is fatigued by over-stimulation of a motor nerve, it is the motor end-plate (the junction between nerve and muscle) which first fails to conduct the stimulus; and Dr. Reid, working in conjunction with Dr. Waller, has shown that when stimulation takes place from the brain, failure by conduction occurs first in the cord, where the ganglionic cell forms a junction between the fibre of the pyramidal tract and the fibre of the anterior nerve-root.

*TREATMENT.*—The treatment of fatigue in all its forms is *rest*, and the restoration of the proper rhythm of nutrition, if this be found perverted, by substituting rhythmical exercises for unrhythmical efforts.

G. V. POORE.

**FATTY DEGENERATION.**—SYNON.: Fr. *Dégénérescence graisseuse*; Ger. *Fettige Metamorphose*.

*DEFINITION.*—The process by which protein elements are converted into a granular fatty matter.

*SEATS OF OCCURRENCE.*—This change may occur in any of the component elements of the body, whether normal or abnormal.

*Physiologically.*—The production of milk from the protoplasm of the mammary cells, and of sebum from the cells of the sebaceous glands, are instances of fatty degeneration. The cells of the corpus luteum are partly in a condition of fatty degeneration; and it is by a similar change in the peripheral cells of the mature foetal portion of the placenta that normal involution of that organ is accomplished. Non-vascular structures, such as the cartilages, the cornea, and the intima of blood-vessels, frequently undergo fatty transformation of part of their substance. In a

less marked form, fatty degeneration occurs in the walls of the uterus and other muscular organs when returning to their ordinary size after temporary hypertrophy.

*Pathologically.*—As a purely morbid process, fatty change is most frequently met with in the muscular tissue of the heart, in the walls of capillaries, and in the urinary tubules; but it also occurs in the central nervous system, constituting the condition known as 'white softening'; in the liver; and in tubercular deposits, cancerous growths, infarcts, and inflammatory products in any situation whatsoever.

*ANATOMICAL CHARACTERS.*—*Physical characters.*—An organ that has undergone fatty degeneration presents the following physical characters. The bulk and weight are generally increased; the consistence is reduced—sometimes to a pulp, as in white softening of the brain; the colour is changed, either as a whole or in the affected portions of the organ, into a buffy or yellowish bloodless hue; and the resistance or firmness is diminished, so that the affected tissue is markedly flabby, and readily yields to pressure. The solid cut surface may appear compact and shining; and the section leaves a greasy stain upon the knife and fingers. When fatty degeneration is greatly advanced, as it may be seen, for example, in the liver, a portion of the organ thrown into water will float.

*Microscopical characters.*—In fatty degeneration the muscular tissue of the heart (see fig. 60) and the walls of capillaries are most suitable—especially those of the brain—for microscopical investigation. The earliest changes in the *cardiac muscle* in fatty degeneration are loss of sharpness of the individual stria, and the appearance of minute particles of oil between the elements. These changes, beginning near the nuclei, spread throughout the fibres in a longitudinal direction, while the particles increase in size, and assume the well-known characters of oil-globules. When the process is advanced, the whole of the sarcous substance is replaced by fatty particles contained within a delicate albuminous envelope. Finally the degenerated fibres either become atrophied by absorption of certain parts of the fat, and so disappear; or suffer rupture with discharge of their contents. The fatty nature of the change is proved by the solubility in ether of the particles that have escaped from the fibres.

Fatty degeneration of the *walls of vessels* is best seen in the capillaries and smallest arteries. The tunics first lose their normal translucency; minute granules appear in their substance; and these increase to form unmistakable oil-globules. Finally, the vessel gives way, and the oily particles and blood are discharged into the perivascular spaces.

In the other organs referred to, the microscopical characters agree with those just described, with certain differences dependent

upon the special structure of each. Thus fatty degeneration of a leucocyte leads to the formation of the body known as a *compound granular corpuscle*, in which the oil-drops finally replace the whole of the protoplasm. In 'white softening' of nervous tissue, the nerve-cells and probably all the nuclei of the part are converted in a great measure into granular corpuscles; and these breaking down into a fatty detritus, the whole constitutes a soft creamy-looking substance, which, as Virchow expresses it, 'is milk in the brain, instead of in the mammary gland.' 'Yellow tubercle' consists in part of cells and nuclei that have undergone fatty degeneration, and of fatty detritus. In the case of the uterus during involution the fat is probably rapidly absorbed, so that the appearances presented to the eye are those rather of atrophy than of replacement of the muscular substance by fat.

**PATHOLOGY.**—We have now to trace whence comes the fat that is found in this form of degeneration, and how. It is evident that in a number of instances—such as the production of milk and sebum—fatty degeneration is a truly physiological change, which is subservient to health when active, while its derangement or cessation constitutes disease. In other cases the process is essentially pathological, as, for example, in fatty degeneration of the heart and white softening of the brain; the functional activity of the part being impaired, or so abolished that the name of *necrobiosis*, or death-in-life, has been given to the condition. The fatty change in the two instances is, however, manifestly one and the same. The condition known as fatty degeneration had long been described, and it has always been a favourite subject with pathologists to discover its nature and its cause. It was generally assumed that the fatty matter present was introduced from without, being deposited from the blood as morbid material in place of the pre-existing tissues which were absorbed. Modern research has demonstrated that this is not so, and that fat is derived from a molecular change in the tissue or textures in which it is found. The subject is one of immense importance, involving the whole field of pathology; and it is but right to state that our acquaintance with the true nature of the process is almost entirely due to the investigations of Dr., now Sir Richard, Quain, which were published in the *Medico-Chirurgical Transactions* for 1850, and with reference to which Sir James Paget has remarked: 'Dr. Quain has candidly referred to many previous observers by whom similar changes were recognised; but the honour of the full proof, and of the right use of it, belongs to himself alone.'<sup>1</sup> Quain's conclusion, as then stated, was that the molecular fatty matter in the degene-

rated fibre was the result of a chemical or physical change in the composition of the tissue, occurring independently of those processes which we call vital. The arguments which he adduced in support of this view were the following: (1) That in the formation of the substance known as adipocere from albuminous material after death, the places of the muscular fibres, blood-vessels, and nerves are occupied by fatty matter which could not have existed in them as such during life. (2) That a true fatty degeneration may be artificially produced *post mortem*. (3) That masses of albuminous material deprived of nutrition in any part of the body, or the centre of non-vascular structures such as tubercle, undergo fatty degeneration to a marked degree. (4) That the circumstances under which fatty degeneration occurs in the living body exhibit impairment of general and local nutrition, such as blood-disorder, or disease of the nutrient vessels.

More than twenty years later (1871) these conclusions were experimentally confirmed in the living animal by the investigations of Professors Bauer and Voit, of Munich. On administering phosphorus to a starving dog, in which the amount of nitrogen (urea) daily excreted had become constant, these experimenters found that the amount of the excretion was thereby increased threefold; that this nitrogen was derived from the albumen of the tissues and not of the blood; and at the same time that three times the normal amount of oil had accumulated in the viscera. This oil could have its origin only in the transformed or decomposed albumen of the organism; the other product being the urea which had been excreted. The same results have been observed in poisoning by phosphorus in the human body.

Many other instances of the formation of a fatty from a nitrogenous body might be adduced if necessary, such as the ripening of cheese; the increased flow of milk on a meat diet; the formation of wax by bees from sugar and albumen; the production of fatty acids and their allies from proteid compounds in the process of pancreatic digestion; the increase of oil in olives by keeping; and the development of a rancid oil in the flake of salmon under similar circumstances. The numerous instances just adduced combine to strengthen the position—which was, however, sufficiently established by Sir Richard Quain—that in true fatty degeneration, the nitrogenous material of the tissues themselves, and not the blood, must be considered the source of the oily matter. It has been said that the circumstances under which fatty degeneration occurs are further confirmatory evidence in the same direction. These must now be considered.

**CONDITIONS OF OCCURRENCE.**—The circumstances under which fatty degeneration occurs are either such as affect the nutrition

<sup>1</sup> *Lectures on Surgical Pathology*, 1st ed. vol. i. p. 107, note.

of the whole system generally, or of a given organ, or portion of it, specially.

*General.*—When the amount of blood in the body is quickly reduced—for example, by severe but not actually sudden hæmorrhage, and in anæmia—death may occur from fatty degeneration of the heart, the voluntary muscles and the other viscera being likewise, but less seriously, affected. Again, general fatty degeneration is frequently due to depraved quality of blood, and especially to the presence in it of certain poisons, such as phosphorus, arsenic, antimony, and the more complex animal-poisons of the acute specific fevers.

*Local.*—Disease of the nutrient artery of a part is the morbid condition most frequently associated with localised fatty degeneration. A good instance of this is furnished by fatty degeneration of patches of the muscular tissue of the heart corresponding with degeneration, obstruction, or compression of a branch of a coronary artery. Another excellent example of the same is white softening of the brain from vascular degeneration. This is analogous to what occurs in dry gangrene, with the exception that decomposition takes place in the latter, probably from exposure to air.

*SUMMARY.*—When we review the circumstances under which fatty degeneration is found to occur, we discover that the condition that is common to them all is interference with nutrition, and especially with the process of oxidation. The red corpuscles are believed to be primarily affected in phosphorus-poisoning; they are numerically reduced in continued hæmorrhage; and they do not reach the tissues in sufficient numbers when the vessels are obstructed, or otherwise diseased. In the cases of the hypertrophied uterus and heart, of the placenta, and perhaps of the corpus luteum, the degeneration is probably due to the decline or cessation of functional activity, and the consequent decrease in the blood-supply to the large mass of protoplasmic structures.

With respect to the *intimate* or *essential* nature of fatty degeneration, it may be stated as highly probable, as far as our present knowledge extends, that the metabolism or decomposition that is constantly going on in living protoplasm is not simple or immediate; but that a primary decomposition occurs of albuminous substances into urea (or its allies) and fat, and a further or secondary decomposition of the fat into carbonic acid and water. If the amount of oxygen furnished by the blood is deficient, whether absolutely or relatively, the primary decomposition of the protoplasm alone may be effected; and the secondary decomposition, or the oxidation of fat into carbonic acid and water, may not occur. The result therefore of an absolute or relative deficiency of oxygen in protoplasmic tissues will be the accumulation of fat within them.

*EFFECTS.*—The physical effects of fatty degeneration of a tissue have been already described under the head of physical characters, being chiefly—change of colour, diminished consistence and resisting power, softening, rupture, dilatation and excavation, and alteration of size. The chief physiological effect is diminished functional power or activity, which is especially marked in muscular parts such as the heart, and in secreting organs, including the kidneys.

*TREATMENT.*—The subject of the treatment of fatty degeneration will be found discussed under the head of the diseases of the several organs which it may affect.

J. MITCHELL BRUCE.

**FATTY INFILTRATION.**—Fat in the form of oily particles is found to be present in excess in the cells of various secreting organs, constituting fatty infiltration. Thus it appears in the epithelium of the intestinal mucous membrane during digestion; in the cells of the liver and biliary passages; and in the kidneys of certain animals—for instance, the cat. When this condition becomes permanent it constitutes a disease. Glandular organs thus affected, as in the case of the liver, assume a buff or yellow colour, and they become softer and more friable than normal; whilst microscopically their cells are found to contain one or more large well-defined oil-globules, which tend to coalesce and occupy the cell. The quantity of oily matter in the cells may, however, vary from time to time, and the infiltration may be either of a transient or of a permanent character. In the one case, the function of the organ may not be materially interfered with; in the other case, the action of the cells may be so far affected as greatly to impair the secreting functions of the organ.

The causes of fatty infiltration are of two kinds—general and local. First, the *general* causes are (a) a superabundance of fatty matters in the blood, such as occurs in persons who indulge in rich food and in beverages containing alcohol; (b) imperfect oxidation, as in chronic tuberculosis of the lungs; and (c), according to some observers, the metastasis of fatty deposits from one part of the body to another.

Secondly, with respect to the *local* causes of fatty infiltration, one is a peculiar affinity or selective power of the cells of certain tissues, by virtue of which they incorporate with their substance oily or fatty matter. This facility has been explained, in the case of the cells of the liver and of the passages traversed by bile, by the presence of that fluid, which, as Virchow and others describe, is a powerfully determining cause of the infiltration of fat into protoplasm. Another local cause of the accumulation of oil in cells is their inactivity or imperfect power of

eliminating it, as is found to occur in the cartilages of the aged, and in inactive or unused muscles.

It must be said here, with respect to the appearance of fat in the last-named situations, that though, in some cases, it is derived unquestionably from the fat contained in the blood or chyle, it may in other instances be derived from the disintegration of the protein elements of the tissues. This subject, however, will be found discussed in the article upon FATTY DEGENERATION.

RICHARD QUAIN.

**FATUITY** (*fatuus*, silly).—Mental imbecility. See IMBECILITY.

**FAUCES, Diseases of.**—See THROAT, Diseases of.

**FAVUS** (Lat. *a honeycomb*).—SYNON.: *Tinea favosa*; *Dermato-mycosis achorina*; Honeycomb Ringworm; Fr. *Teigne faveuse*; Ger. *Erbgrind*.

**DEFINITION.**—A chronic, contagious, parasitic disease of the skin of man and some animals, caused by the growth of the Achorion fungus (discovered by Schönlein in 1839), and characterised by the formation of peculiar yellow crusts, and by the occurrence of inflammatory and often atrophic changes.

**ETIOLOGY.**—Favus is somewhat less contagious than ordinary ringworm, and individual predisposition has a marked influence in its spread. The young are most prone to attack, and children living amidst sordid surroundings. Propagation occurs by direct contact and inoculation, and transmission of the complaint has been observed to and from mice, to the rat, cat, dog, fowl, guinea-pig, rabbit, horse, and ox. In England, where it is uncommon, favus is seen mostly in foreign immigrants; but it occurs more frequently in Edinburgh and Glasgow. It is comparatively common in the southern provinces of France and Italy, and amongst the male Jewish population of Russia, Poland, Galizia, and the Levant; the Mohammedans of Turkey, Asia Minor, Syria, Persia, Egypt, Algiers, and Morocco; also in parts of India, China, and Brazil.

**SYMPTOMS.**—The fungus develops beneath the upper layers of the epidermis, around the hair, setting up some inflammation, and presently appears as a little yellowish elevation. In some weeks the latter forms a characteristic, sulphur-yellow, sub-epidermic, lentil-sized, umbilicated disc (the *godet favique*, *scutulum*, *favus*), lying in a red, moist, cup-like bed fashioned by the pressure of the growth, and traversed by a hair. Gradually the fungus invades the hair-sheaths and then the hair, growing perhaps three or four centimetres above the level of implantation. The bulb usually remains free, and indeed the hair in favus is not

invaded so quickly or abundantly as in trichophytosis, and, as a rule, is not nearly so disintegrated. The hairs become lustreless, dusty-looking, loosened, and finally atrophied and distorted. A characteristic mouldy smell is observable, which must be carefully distinguished from the stale scent of old dried-up pus. Favus may attack hairy regions, non-hairy parts, and the nails; but the scalp is far the most important site affected, on account of the intractability of the disease there, and the ensuing disfigurement. The characteristic cupuliform discs may attain to a diameter of about half an inch or more. They may remain isolated and disseminated, or be aggregated and more or less confluent. As they age, the colour fades or darkens by the admixture of exudations, and the consistence becomes more friable. They tend to lose their characteristic aspect, crumble and fall, to be replaced by others more or less imperfect. In course of time most irregular and atypical changes result from the effects of scratching and excoriation, and from pustulation. Secondary glandular inflammation can then arise. Finally, a disfiguring baldness may result; and as this occurs, the disease gradually dies out, but only after many years.

Regions of the trunk, extremities, or face, commonly spoken of as non-hairy, may be attacked primarily or often secondarily to the scalp. Here the favi are surrounded by inflammatory halos, or preceded by a ring-worm-like eruption.

One or several nails of the hands, or even of the feet, may be inoculated, and then the favi form beneath, and gradually erode the nail. At the same time the nutrition of the latter is much impaired, and the structure disorganised.

**DESCRIPTION OF THE FUNGUS.**—The mycelium is composed of flexuous, ramified, tubular, partitioned, and articulated filaments. When fructifying, the tubes are charged with granules, with nuclei, and with perfect nucleated gonidia or spores. Both the mycelium and the abundant gonidia are characterised by a great diversity of size and form. The gonidia are mostly rounded and oval, and may be isolated or united in chains. It is now established that the fungus can be distinguished in cultures; and when inoculated from animal to animal, and to man, it always gives rise to the characteristic clinical appearances. The *godets* consist of mycelial threads branching towards the central part, and then terminating in chains of gonidia and granules.

**DIAGNOSIS.**—In the various forms of favus where at some time or other more or less well-marked *godets* are observable, the diagnosis is clear; and the peculiar smell, the persistence of the malady, the condition of the hairs, and the occurrence of the disease in other members of the family, will attract

attention. In old-standing cases obscured by age or complications it is necessary to search thoroughly for the fungus, and to bear in mind the advice to be always on one's guard in the presence of a persistent, rebellious scalp-affection, simulating psoriasis, eczema, seborrhœa, and the *folliculites décalvantes*.

**TREATMENT.**—Appropriate measures are necessary to counteract any disturbance of the general health that may be present in favus. At the outset all favic and other crusts and accumulations should be thoroughly removed by the usual softening and cleansing methods, and the hair should be completely cut away, and kept so. Mild antiseptic dressings may then be applied, to subdue any inflammation, or heal excoriated surfaces. This accomplished, the further treatment is nearly identical with that for ordinary ring-worm (*see* TINEA TONSURANS). Cases are often most rebellious. Favus of non-hairy parts is much more amenable. When the nails are affected it is necessary to remove mechanically as much of the diseased part as possible, and then thoroughly rub in, or keep the part soaked with, parasitocides.

T. COLCOTT FOX.

### FEBRICULA (*febricula*, slight fever).—

**SYNON.**: Fr. *Fébricule*; Ger. *Febricula*.

**DEFINITION.**—Simple fever, of one (*ephemera*) or not more than a few days' duration; not preceded by any one known invariable antecedent; and not attended by any one definite organic lesion.

It may well be doubted, however, whether such a thing as simple fever, in the strict sense of the term, exists; anyhow it must be one of the rarer forms of disease. The conditions which, from our necessarily imperfect knowledge, it is convenient to call febricula are numerous and of great practical importance. They may be somewhat roughly grouped as follows:—

1. Abortive or incomplete forms of some one or other of the specific continued fevers—namely, typhus, typhoid, or relapsing. The writer's own experience leaves no doubt in his mind that such irregular forms are met with during epidemics of these diseases.

2. Instances of some of the exanthemata, especially scarlatina and modified variola, in which the usual rash is either absent or so slight or brief as to pass unnoticed.

3. Intermittent fevers, in which for some reason or other the paroxysms do not recur, or only at uncertain and distant intervals.

4. Cases in which the local symptoms usually attending certain forms of fever are very slight or very obscure, and therefore difficult, perhaps impossible, to detect. Instances of this occur in connexion with tonsillitis, erysipelas, rheumatic fever, influenza, and tubercular disease.

5. Cases in which considerable febrile

movement is present during the development of the primary as well as of the secondary symptoms of syphilis, and of which it is not easy to ascertain the real cause.

6. Fever as the consequence of exposure to a high external temperature—for instance, the *febris ardens* of tropical climates (Murchison); and of violent and prolonged muscular exertion.

7. Fever as the consequence of irritation of any organ or tissue, such as of the stomach by indigestible matter, of the colon by scybala; or of catarrh of a mucous surface—for example, urethral fever.

8. Certain ill-understood but not uncommon disorders of nervous centres, cerebral, spinal, or sympathetic, which are often followed by febrile movement.

**ANATOMICAL CHARACTERS.**—Fever, however caused, which runs high, produces congestions and tissue-changes in the viscera, especially in the lungs; but, in view of the short duration of febricula, it would in most cases be impossible to decide whether any pathological changes found after death were the consequence or the cause of the febrile movement. It is possible, but not yet proved, that there may exist some contagion capable of producing febricula, and febricula only.

**SYMPTOMS.**—Febricula is characterized by a rise of temperature, rarely exceeding 102.5° F., but sometimes, especially in cases due to exposure to heat, reaching 105° F. or even higher, although only for a short time. The access of fever may be gradual, or marked by slight rigors; and some or all of the common clinical symptoms of fever may be present in varying proportion and in greater or less degree, such as—general malaise; dry skin; frequent pulse, amounting to 100 or 120 per minute; tongue furred, with a more or less distinct, central, dry, reddish-brown streak; thirst, loss of appetite, and nausea; constipation; scanty, high-coloured urine; and headache, intolerance of light, slight deafness, restlessness, sleeplessness, and slight delirium at night.

**DIAGNOSIS.**—The diagnosis of febricula rests upon the exclusion of all the other recognised kinds of idiopathic or of symptomatic fever. As a matter of practical diagnosis at the bedside, almost every disease attended by rise of temperature is now and then, at its outset, mistaken for febricula.

**PROGNOSIS.**—The prognosis depends upon the degree and duration of the pyrexia, but in this country is almost always favourable.

**TREATMENT.**—In the absence of any special indication, rest in bed for a day or two, liquid food until the desire for solids returns, and, if constipation be a marked feature of the case, a moderate dose of some mild purgative, will be sufficient. It is, however, always prudent to remember that what seems to be febricula may be the beginning of some serious and perhaps highly infectious disease.

Cooling drinks, such as citrate of potassium in effervescence, liquor ammonii acetatis with a little spirit of nitrous ether; or nitrohydrochloric or dilute nitric acid (one drachm to a pint of water) with some fresh lemon-juice added, may be given according as the one or the other is grateful to the patient. Anything like active treatment, except sponging the skin or the use of the cold or tepid bath in cases of heat-fever, is unnecessary, rarely does good, and is almost always positively injurious.

J. ANDREW.

**FEBRIFUGES** (*febris*, a fever; and *fugo*, I drive away).—SYNON.: Antipyretics.

**DEFINITION.**—External applications or internal remedies which tend to lower the bodily temperature, when it has been abnormally raised by the processes of fever.

**ENUMERATION.**—The principal febrifuges, given in the order of their activity, are:—Cold Baths; Cold Affusion or Wet Pack; Alcohol; Diaphoretics; Salicylic Acid and its Salts, Quinine, Digitalis, and Aconite; Salicin, Phenazone, Acetanilide; and Water and Diluents generally.

**ACTION.**—Following Professor Binz, we may divide febrifuges into two classes:—(1) those which directly withdraw heat from the fevered organism; and (2) those which lessen its production.

1. In the first division we must give the foremost place to cold baths, the cold pack, and cold sponging, which powerfully abstract caloric from the surface of the body, and rapidly cool down the blood. Diaphoretics and alcohol act more feebly in the same direction, by dilating the cutaneous arterioles, and thus allowing the mass of the circulating fluid to be effectually exposed to the chilling influence of the air. See COLD, Therapeutics of; and DIAPHORETICS.

2. Secondly, we have to consider those drugs which actually check the febrile condition itself, by diminishing oxidation, or by lessening the rapidity of the circulation through those parts of the body in which the increased tissue-change is taking place. It is probable that we must explain the antipyretic properties of such drugs as quinine by their specific influence over the germs on which malaria depends; and perhaps the progress of science may enable us in the near future to nip febrile processes in the bud, by paralysing or destroying the bacilli which may start the chain of morbid processes which raise the temperature and depress the powers of life. The free use of water tends to promote excretion, and thus to remove the products of oxidation. Blisters possibly act by causing contraction of the vessels in the inflamed part.

**USES.**—Antipyretic treatment is not much adopted in this country as a matter of routine, holding as we do that temperatures raised within certain limits are not *per se*

elements of danger, and that, even although we may effectually cool down our patient, the progress of the disease may go on quite unchecked. But prolonged fever causes excessive tissue-change and fatty degeneration of the heart; and when the thermometer registers 105° F., and still tends upwards, we know that dangerous limits are reached, and that as a rule life is not long sustained above 107° F. It then becomes our duty to interfere; and this is best done by plunging our patient into a bath at 95°, and gradually cooling it down to 65°. When the temperature descends to within 4° or 5° of the normal we remove him to bed, remembering the dilatation of vessels which must follow the contracting effect of cold, and the consequent cooling process which must continue to go on. Here, as in all febrile conditions, the thermometer is our surest guide, and we must be directed by it as to when to resume the treatment, for frequent repetition may be needed, and on the Continent as many as 200 baths have been given in the course of a single illness. Along with this the Germans combine the use of large doses of quinine; but, notwithstanding the marked tolerance of the drug under pyrexial conditions, the danger of perilous depression from such free medication is no imaginary one; and, putting ague apart, we find this valuable drug most beneficial in such fevers as seem to owe their origin to septic poisoning. Digitalis is not a powerful antipyretic, and in large doses is too disturbing to the heart, and too apt to produce gastric derangement, to inspire much confidence; but phenazone causes profuse perspiration, and is much used in febrile disorders on account of its certain and rapid action, and acetanilide is effectual in smaller doses. The influence of salicylic acid over acute rheumatism is remarkable, as it seldom fails to reduce temperature and relieve pain in forty-eight hours; but in other feverish conditions its beneficial action is by no means so well-marked. Salicin also has numerous advocates, who prefer it to the salicylates as being less depressing to the circulation. Iron is of value in erysipelas, and exerts some controlling power over acute rheumatism. Aconite and diaphoretics are of undoubted service in aiding the defervescence of some of the minor febrile disorders.

R. FARQUHARSON.

**FEIGNED DISEASES.**—No insignificant part of the real difficulty in the practice of our profession depends on what we may call feigned diseases. The art of diagnosis consists in the power of recognising morbid conditions with skill and promptitude; and in proportion to the natural sharpness and well-digested experience of the medical man is his success in the discrimination of one symptom from another which resembles it more or less superficially. Many disorders

possess a strong family likeness in their very early stages, whilst others may prove deceptive throughout their whole course; and if to this we add the efforts at deception occasionally resorted to by impostors, we see the caution which must of necessity be adopted by those who exercise their calling within wide limits. In considering, therefore, the subject of feigned diseases, a greater amount of order may attend our studies if we adopt the following simple classification:—

1. Those diseases which naturally resemble one another, and in the deception attending the diagnosis of which the patient has no share.

2. Those diseases which are also difficult of diagnosis, but in which the patient involuntarily deceives under some morbid nervous impulse.

3. Cases in which the patient sets himself deliberately and elaborately to deceive those around him.

1. Under this heading we may perhaps include the exanthemata and other acute feverish affections, which are confessedly difficult of diagnosis before the eruption or other marked points of difference are fully established. Important though it may be, in the case of public schools or large bodies of men, to act promptly in the face of such an emergency, the medical man will often feel himself compelled to postpone his decision; but he should at the same time act on the defensive by the timely exercise of quarantine and hygienic precautions. Some diseases, again, are difficult to distinguish from one another, even after their prodromata have passed away, and among these we may include small-pox and pustular syphilis, which occasionally cause more than a shade of suspicion to pass over the mind; whilst mild variola and severe varicella must always have too many points in common to render them otherwise than stumbling-blocks even to the initiated. Various forms of roseola may closely simulate measles; scabies is often hardly to be picked out from amongst the eruptions which its irritation causes; whilst throat-affections may apparently overlap each other and engender the idea of diphtheria where nothing more than superficial or aphthous ulceration really exists. But it is when the ailment under which our patient labours resembles something else during its whole career that mistakes are naturally most likely to arise. We are frequently shocked with some scandal in which the innocent victim of brain- or other organic disease has been consigned to a police-cell, and where the plea of drunkenness has been attempted to be sustained by the guardians of the public peace. So difficult is it to make a really trustworthy diagnosis between the coma of alcohol, of uræmia, of opium, and of certain apoplectic conditions, that the truly cautious and well-informed practitioner would prefer

not to attempt to do so offhand. It is impossible to lay down any general rules, but we may remember that alcohol in poisonous doses lowers the temperature and dilates the pupil; that in uræmia an examination of the urine will put us in the right track; whereas opium will produce a contracted pupil; and in cerebral hæmorrhage some elevation of the body-heat may not improbably be observed.

But all these points may fail us from time to time, and we had best act at all times as though the case were really a serious one, and requiring treatment by all the best resources of the medical art.

A very little consideration will enable every experienced practitioner to recall other instances of this sort of natural mimicry: of the difficulty he must often have experienced in deciding between syphilitic and other brain-affections; of the close affinity between pulmonary consumption and dilatation of the bronchial tubes; of the resemblance between specific and malignant ulcerations; between various diseases of the testicle, the bladder, and the stomach, respectively. All these form part of the regular teaching of medicine and surgery, and will be found treated of elsewhere.

2. We must now consider the cases in which diseases are feigned, not by the direct action of the patient himself, but because he is unable to resist the vagaries of his weak and excitable nervous system.

Problems of the greatest complexity and difficulty are here presented to the medical man, and require for their due solution much tact and experience. Functional affections so closely simulate organic disease under these circumstances that suspicion is often completely disarmed, and treatment adopted the very opposite of that which would most probably prove curative. Hysteria, in its protean forms, supplies the greater number of these cases, and may very closely simulate a large variety, more especially, of neurotic conditions (*see* HYSTERIA). Paraplegia, incontinence of urine, joint-affections—in short, almost any disease which does not admit of palpable objective demonstration—may thus be feigned, and very severe treatment may even be adopted under the belief that real organic changes have to be met by the usually appropriate remedies. It is only necessary for us to refer thus briefly to these perplexing cases here; but it must always remain an interesting problem as to how the mechanism of causation here works, so to speak, and whether the patient actually suffers the acute pain of which she complains so forcibly. Sympathy, as we well know, however, is quite thrown away when dealing with these persons; and apparent roughness, with nerve tonics, and mental discipline, will often effect a cure, when the most elaborate combinations of other drugs ignominiously fail. A sudden shock, the pressure of poverty, or the absolute necessity for immediate exertion, will

often effectually and permanently arouse the bedridden hypochondriac of many years, and restore him to his friends as a useful member of society; and we need never despair of success even under apparently hopeless circumstances. And although in minor measure the hypochondriac may fancy that every organ in succession is the seat of disease, and may even succeed in thus imposing on the unwary, the experienced practitioner will speedily detect the fiction, and be able to relieve the unhappy sufferer from the weight of his woes. See NEURASTHENIA.

But let it not be forgotten that 'expectant attention,' or the constant direction of the mind to the supposed morbid condition of any particular organ, may actually catch the unconscious deceiver in his own net by converting mere functional disturbance into organic disease.

3. To the third division of our subject can the term Feigned Diseases perhaps alone strictly be applied. Here we are met face to face with deliberate and premeditated imposture; and there is nothing for it but to match our own wits against those of the deceiver, and to thwart his native cunning by the superior sharpness of science. Now, there is nothing in the history of medicine more remarkable than the elaborate expedients adopted, and the amount of actual discomfort and suffering endured, by persons who have been desirous of escaping military or other duty. The exhaustive works of Gavin and Marshall, and Boisseau and others, give us details no less ingenious than interesting of these devices; but it is curious to note in how limited a range the more traditional modes of imposture seem to run, and how the same old stories are made to do duty over and over again. Thus we read of blindness, and deafness, and epilepsy, and paralysis being carefully imitated, and can hardly withhold our admiration from the astonishing tenacity with which the apparent symptoms were duly maintained. Incontinence of urine, dysentery, hæmoptysis, jaundice, and insanity were among the most favourite rôles in the repertoire; and ingenious as were the preparations for duly sustaining the part, no less ingenious were the means for detection, which usually proved successful. However carefully the impostor had studied his character, some little point was usually omitted. The yellow conjunctiva of jaundice can hardly be feigned; the incontinence of urine was generally found to be attended by an expulsive effort; the blood apparently proceeding from the lungs was by no means intimately mixed with the pulmonary mucus; the blindness, or the deafness, or the paralysis was not proof against some sudden shock or mental impression. Most of the cases so carefully described by writers on military medicine are now mere matter of history, and are hardly likely to

occur again. And the reasons for this are twofold. First: the inducement for deception is practically gone. In former days, when the soldier's pay was small and his hygienic condition bad, discharge from the service as an invalid was eagerly prized as a means of escaping irksome duty; but matters have greatly changed for the better of late years. Not only are the emolument and the comfort of our army vastly increased, but short service and the reserve enable soldiers to retire early into civil life; whilst the abolition of bounty has removed the principal pecuniary inducement for frequent desertion and re-enlistment. It is now found much easier for a man simply to desert than to go through any elaborate process for the personification of disease. Again, the savage process of forcible impressment for naval service was naturally productive of many attempts to escape from the hard work and ferocious discipline of our men-of-war. Secondly: the progress of science and improved means of diagnosis have rendered the task of the impostor difficult, if not well-nigh hopeless. Feigned blindness can hardly resist the test of the ophthalmoscope; electricity will clear up many apparently anomalous nervous symptoms; the stethoscope and the sphygmograph will tell us the real condition of the heart; and careful observation will detect the rougher attempts to deceive. Again, malingering may often be exposed by examination under chloroform or ether. We are not likely now to be deceived by a piece of liver tied to the breast to simulate cancer, or by an artificial nasal polypus; but Mr. Gould records in the *Lancet* the case of a young woman sent to hospital for double buccal tumour, in whom on examination the swellings were found to consist of tightly wound balls of thread forcibly inserted between the teeth and the cheek. Mr. Anderson, of Richmond, fairly capped this in a subsequent number by narrating the vagaries of a schoolgirl who had produced a state bordering on gangrene of the hand by a ligature of ribbon resolutely applied to the forearm; and it is evident that although skin-diseases and ulcerations may be made or kept up by local applications, we only require a suspicion to cross our minds to put us on the right track for discovery.

We are not, however, to suppose that all attempts at deception have finally passed away, that feigned diseases are now things of the past. Anyone whose practice lies among prisoners, or soldiers, or schoolboys, or the sufferers from railway accidents, will very soon be convinced to the contrary (see RAILWAY INJURIES). Experience, however, will speedily show him who the schemers are, and enable him to circumvent their endeavours; and the range of symptoms simulated will soon be found to be singularly narrow. Subjective sensations are, of course,

very difficult to detect; and if a headache, or pain in the back or leg or arm, be complained of by the sufferer, real or assumed, we may often find it best for our own reputation to give him the benefit of the doubt. Whilst proceeding, therefore, with due caution, the practitioner must endeavour to hold the balance between an excess of suspicion and a too credulous attitude, remembering that the good of society and of the public service must be fairly considered, whilst all care must be taken not to confound the innocent with the guilty in dealing with disorders which ingenuity has occasionally been enabled to feign. ROBERT FARQUHARSON.

**FEIGNED INSANITY.**—See INSANITY, Varieties of.

**FESTER.**—A superficial suppuration, resulting from irritation of the skin; the pus being developed in vesicles of irregular figure and extent. The suppurating inflammation caused by a thorn or splinter of wood forced into the flesh is a common example of a fester.

**FEVER** (*ferveo*, I am hot).—SYNON.: Pyrexia; Fr. *Fièvre*; Ger. *Fieber*.

**DEFINITION.**—One of the most remarkable facts in connexion with disease is the rise of temperature which is attendant upon almost every disturbance to which the body is subjected. The rise of the temperature of the body, when it attains a certain height, and lasts a certain time, is called Fever; and is accompanied by derangement of function, attributable to the febrile condition itself, and in a measure independent of the initial cause.

**GENERAL CONSIDERATIONS.**—Fever plays so important a part in acute disease generally, is accepted so universally as a mark of the severity of the disease, and so often presents itself as apparently the chief antagonist with which the physician or surgeon has to contend, that the attempt to penetrate the secret of its essential nature has always been a favourite task, and every school in every age has had its theory of the febrile process. It is only, however, within comparatively few years that exact measurement of the body-heat by the clinical thermometer, combined with chemical examination of the various excretions at different temperatures, and aided by the experimental method of investigation, has furnished the data for such a theory (see THERMOMETER). A minute description of fever in the abstract, distinguishing, as would be required, between phenomena proper to fever and phenomena due to the condition or lesion on which the fever depended, would be lengthy, and so crowded with qualifications and exceptions as to be vague and unsatisfactory. The attempt, indeed, would have a more radical defect. Either some variety of fever must be taken as a type to which other forms are referred, which is vicious in principle; or all the phenomena of all febrile

conditions must be enumerated and classified, which would confound the accidental with the essential, and would result in a heterogeneous collection of facts without due relation among themselves.

A mere outline therefore will be given of the principal deviations from normal functional action observed in fever, and the space set apart for the subject will be reserved chiefly for an exposition of what is known of the nature of the febrile process.

**DESCRIPTION.**—In every attack of fever there are traceable the three stages of invasion, domination, and decline, with or without an antecedent period of incubation. They may all be run through in the course of a few hours, as in a paroxysm of ague, or they may extend over weeks.

The period of invasion is characterised by a rising internal temperature, while the surface may remain cold and pale, the patient feeling chilly and suffering from rigors or shivering; the pulse is frequent, but generally small and long, from contraction of the arteries. During the dominance of fever the temperature remains high, the skin is hot, and the shiverings are replaced by a subjective sense of heat; the pulse is now large and bounding from relaxation of the arterial wall. The decline is indicated by a falling temperature, a softer and less frequent pulse, and by a return towards normal conditions generally; it may be initiated or accompanied by a critical sweat or other evacuation. Death may take place at any period of the disease.

Taking the temperature as the index of the duration and character of each stage, we may find it in the first stage rising abruptly or gradually, continuously or with remissions. If the invasion extends over several days as in enteric fever, nocturnal exacerbations and morning remissions are, as a rule, observed. A rapid rise of temperature is usually continuous, or nearly so. When the opportunity occurs of making the observation, as in intermittent or relapsing fever, or when fever is experimentally induced in animals, or in man by surgical operation or accidental septic inoculation, the increased heat is found to be the initial phenomenon, preceding the rigors and all other symptoms.

The end of the period of invasion, and the setting in of the stage of dominance, is more distinctly marked by the change in the character of the pulse, and by the determination of blood to the surface, together with the substitution of the subjective sensation of heat for that of cold, than by the thermometer.

During the dominant stage the temperature remains at, or oscillates about, a given point, and the fever is considered to be moderate if the morning temperature is 102° F. or under, and the evening not above 103°; to be high when it ranges between 103° the morning and 104° in the evening; and to be

severe when these limits are exceeded; while, with rare exceptions, a temperature of  $106^{\circ}$  indicates great danger. As the stage advances, the heat may gradually rise or fall; the oscillations being slight or considerable, and at times irregular and extreme. Except when the fever is due to local inflammation, or to continual entry into the blood of morbid particles or fluids, the duration of the dominance is usually in proportion to the time occupied by the invasion.

The decline again is generally abrupt, and has the character of a *crisis* when the invasion has been rapid, and is protracted when it has been gradual.

A fatal termination may be ushered in by hyperpyrexia; more commonly the temperature falls below the normal point and there is collapse.

The pulse is always increased in frequency by fever, but while during the height of the disease there is usually some relation between the body-heat and the pulse-rate, the pulse is often extremely frequent before the temperature has reached its height during the invasion, and it does not in all cases fall with it *pari passu* in the decline. The different stages are marked rather by differences in the character of the pulse than in its rapidity; during the period of invasion the arteries are more or less in spasm, and the pulse is small and long; during the dominance, with certain exceptions, the arterial walls relax, the vessels are large, and the pulse sudden, short, and dicrotous; as the fever declines, the arteries are still further relaxed, but the action of the heart is less powerful, so that the pulse becomes softer.

Respiration is frequent, following as a rule the pulse; the amount of carbonic acid expired is greatly increased.

The tongue is generally more or less furred, its appearance varying with the degree and kind of fever and with its cause. It becomes brown and dry, or unnaturally red, in protracted and adynamic fever, when the teeth and lips may also be coated with *sordes*. There are almost always thirst and loss of appetite. The bowels are usually confined.

The secretions are all more or less modified. The perspiration may be greatly increased, as in acute rheumatism; more commonly it is checked, causing the skin to be dry and burning. The amount of urine will vary to a certain extent inversely with the amount of perspiration; but the tendency is to increase, and the solid organic matters—urea and other nitrogenised substances—are always considerably augmented in quantity. The chloride of sodium, on the contrary, is diminished.

The characteristic nervous phenomena of the stage of invasion are rigors, which may be slight, and represented only by shivering or chilly sensations, or, on the other hand, may be intensified to convulsion. Severe

headache is more common at this period than in the later stage, and there is usually considerable depression. When the fever has reached its height the rigors will have ceased, and there may be little or much delirium according to the severity of the attack, the idiosyncrasy of the patient, or the kind of disease giving rise to the fever.

**PATHOLOGY.**—The description of the febrile state has been abbreviated in order to leave place for a discussion of the nature and cause of the febrile process.

This will be facilitated by a brief reference to the production and regulation of the heat of the body in health, and would be comparatively easy had physiologists arrived at a complete and satisfactory solution of this problem. In the normal state the main source of animal heat is blood- and tissue-combustion. It may perhaps be well to say here once for all that the terms 'combustion' and 'oxidation' are employed as conveniently short expressions for the disintegration of complex chemical and structural molecules by which heat is liberated, and not to convey the idea of direct combination of oxygen with the carbon and hydrogen of the blood and tissues. Another very slight and unimportant cause will be obstructed motion of the blood in the capillaries: of direct conversion of nerve-force into heat we know nothing definite. The interesting and difficult part of the question is that which relates to the regulation of the temperature. It has been found that the changes which evolve heat are most active in muscle, in the nervous structures, and in the abdominal viscera; while in the lungs any combustion which may take place is not more than will counteract the loss of heat by evaporation and by the expired air. The skin, on the other hand, is the great cooling agent; there is little combustion of its structures, and it is continually losing heat by conduction when the surrounding temperature is low, but still more abundantly by evaporation under all conditions of external temperature. Heat is thus abstracted from the blood circulating in, and immediately beneath, the skin. At first sight, then, it would seem that the mechanism by which the temperature is regulated was extremely simple, and that it was to be found in the vaso-motor system of nerves. There being an internal heat-producing mass of tissue, and an external refrigerating surface, in order to raise the temperature, the arterioles of the skin are contracted, shutting off the blood, while those of the deeper structures are relaxed, allowing it to reach them in greater abundance; in this way a double influence is exerted—less heat is lost by the skin, and more is produced in the muscles and other internal parts. Conversely, the temperature would be lowered by flushing the skin with blood—which would thus be exposed to cooling influences—and divert-

ing it from the heat-forming, deep-seated structures. This explanation, however, is inadequate. It is true that the distribution of the blood, superficially or deeply, by means of the vaso-motor nervous system, contributes largely to the regulation of the temperature; but heat-production in muscle or gland is not directly proportionate simply to the amount of blood circulating through it. Tissue-combustion, and consequent evolution of heat, is excited or repressed by cerebro-spinal nerves which do not govern the arteries. The nervous stimulus which excites contraction in muscles determines in them at the same time evolution of heat, and this heat-production under nerve influence may be excited independently of contraction. The nervous system thus intervenes directly in heat-production chiefly by its action on the muscles, as well as indirectly through its influence on the circulation. This is not the place to discuss the question whether there are special thermal nerves and centres, but it seems probable that the muscles as thermogenic and as motor agents are under the control of the same central nervous mechanism.

Taking the increased heat as the characteristic of fever, the first question which arises is whether this is due to increased production of heat, or to diminished loss. While the diminished circulation in the skin, in the early stage, will obviously tend to retain heat within the body, there is now no room for doubt that there is increased heat-production. The temperature rises in spite of profuse perspiration, when, of course, heat is very rapidly lost, as in acute rheumatism, or when perspiration has been induced by jaborandi before a paroxysm of ague (Ringer); and it has been shown by direct experiment that in fever a man raises the temperature of a given quantity of water in which he is immersed more quickly, and to a higher point, than in health (Liebermeister). It is unnecessary to give other proofs or further refutation of the hypotheses which explain the heat of fever solely by diminished escape of heat from the body.

It may further be taken as certain that the immediate cause of the increased generation of heat is increased blood- and tissue-oxidation. This is shown by the increased products of combustion given off in the different excretions. The febrile elevation of temperature is attended at once by increase in the amount of carbonic acid expired. This is more marked during the rise than when the heat has attained its maximum, because the increasing temperature expels the gases of the blood, and the greater rapidity of the circulation sends the blood more freely and quickly through the lungs, and exposes it more to the air. At first there will thus be eliminated not only the carbonic acid formed under the influence of the febrile process, but that which was held in solution by the

cooler blood, and is driven off as its temperature rises; when the expulsion of dissolved carbonic acid is completed, the amount excreted will be diminished by so much, but it still remains larger than at the normal temperature.

A similar indication of increased tissue-combustion is furnished by the urine. The amount of urea is usually absolutely increased, notwithstanding a diminished consumption of nitrogenised food; or if the urea itself is not excreted in larger quantity, there is more nitrogenised waste in other forms. The total of nitrogenised matter contained in the urine is always augmented by fever.

While, however, the products of combustion show that rapid metabolism is going on, it is not clear that it is adequate to account for the whole of the heat evolved; and Dr. Ord has advanced the luminous hypothesis that the energy normally absorbed by the constructive operations taking place in the tissues is set free through the suspension of these processes by fever, and takes the form of heat.

The real difficulty of the problem arises when we inquire what is the cause of the increased tissue-combustion, and especially how the febrile heat is regulated. It has been already stated that the distribution of the blood to the deep structures and organs and to the skin respectively is not a sufficient explanation of the physiological balance of heat; but it might be supposed that the greater rapidity of the circulation in fever, renewing the supply of oxygenated blood within the structures more frequently and more freely, would account for the greater oxidation. The rise of temperature, however, is not in proportion to the flow of blood through the vessels, and hyperpyrexia is often coincident with a failing circulation, the heat of the body, indeed, apparently in some cases actually increasing after death.

Dr. Donald MacAlister has done much to elucidate the entire question in his *Gulstonian Lectures*, by bringing out more distinctly the thermogenic function of the muscles, and the thermotaxic or heat-regulating power of the nervous system, which operates through its influence upon thermogenesis in the muscles on the one hand, and upon the thermolytic action of the skin on the other.

One step towards the solution which may be considered certain is that the nervous system is concerned in the maintenance of the heat of fever. Each disease has its own characteristic range and variations of temperature; and this fact alone, that febrile heat is not vague and irregular, but that there is the substitution of a morbid for a normal balance, is evidence of nervous control. Numerous observed facts and experiments point to the same conclusion.

Another item of positive knowledge obtained by experiment is that pyrexia may be

excited by the introduction into the blood of septic or other matters, which, it is important to note, need not be particulate, but may be diffusible fluid. The increased heat may therefore be independent of capillary embolisms, and of bacteroid or other organisms.

Now in disease or after injuries we have almost always both causes in possible operation—an impression on the nervous system, and the entry of altered organic matters into the blood. In endeavouring to assign prominence to one or other, we have, on the one hand, such facts as the hyperpyrexia of cerebral lesions, which cannot be due to blood-contamination, and, on the other, the teachings of antiseptic surgery, which demonstrate that absorption of putrescent discharges is the great cause of surgical fever. It still remains to be determined whether the presence in the blood of foreign matters gives rise directly to increased activity of oxidation, or whether the poison, as we may call it, produces this result through its action on the nervous system, either by affecting the nerve-centres themselves, or by producing irritation in the capillaries, which is carried to the nerve-centres, and reflected along efferent nerves. In the present state of our knowledge this question cannot be definitely settled.

If a theory of the febrile process is to be formed, it must be based upon a theory of the relation between the nervous system and the processes of nutrition and oxidation, and especially the latter. Numerous facts of disease and of experiment point to the conclusion that the circulation of duly oxygenated blood through the tissues at the usual rate would, without some check to oxidation, result in more rapid tissue-change, and the production of a higher temperature than the established norm. The restraining power is supplied by the nervous system, the loss of this influence being illustrated in hyperpyrexia. The mode in which the nervous system acts may be represented as being through the tension maintained in the nerve-centres. All nervous actions have the character of phenomena of tension, and the tension generated in the cells is sustained in the nerve-fibres to their peripheral terminations, where they are merged in the structures, and so blended with them that all nutritive and oxidative changes are common to the nerve-endings and the tissues in which they end. If we suppose that the nerve-tension can modify chemical action, as can electrical tension or thermal conditions, and that, *vice versa*, the nutritive and oxidation changes in the tissues can influence the tension of the nervous structures, we can represent to ourselves the interaction between the nervous system and the blood and tissues in the febrile process. When from disease or injury of the great nerve-centres their power of maintaining tension is lessened or abolished,

and their influence proportionately diminished, so that the affinities of the blood and tissues have unrestricted play, the result is hyperoxidation and pyrexia. When, on the other hand, septic matters or other substances are introduced into the blood, acting as ferments or in some other way, they increase oxidation, and directly raise the temperature, overpowering the restraining influence of the nerves until this is reinforced, which may possibly occur through increased evolution of energy, resulting from the increased activity of metamorphosis. We cannot, however, here develop or fully elaborate this hypothesis.

TREATMENT.—The treatment of fever is of course primarily directed to the removal of the cause on which it depends, but together with the measures adapted to this end are usually employed means for the moderation of the febrile process as such, and these may at times take the first place. We can do little more than mention the more important of them, taking first what may be called the general methods, and premising that rest in bed, simple food, &c., are assumed to be understood. Venesection is now scarcely ever practised as a means of combating fever. Purgatives are often useful, as are also diaphoretic and diuretic salines, with abundance of water to drink, either alone or in the form of some agreeable *tisane*. Free action of the secretions, which is the object of these remedies, is of service in removing the increased products of oxidation, the water taken co-operating by acting as a solvent and vehicle; and it is possible that medicines which promote this activity may directly bring down the temperature. When, for example, perspiration has been induced, a coincident fall of temperature may be due more to some change antecedent to the perspiration, than to the loss of heat by transpiration and evaporation.

Of special measures for the reduction of febrile heat when this is becoming dangerous, either from its intensity or duration, the first to be mentioned is the cool or cold bath. This should be resorted to in all cases of hyperpyrexia, from whatever cause; its efficacy, first established in the high temperature of acute rheumatism and enteric fever, has been proved also in cases of septic hyperpyrexia after ovariectomy, and even in injuries to the brain. Here the water may be positively cold. When the bath is employed to control temperature, not dangerous from its height, but from its duration, as in enteric fever, the temperature need not be lower than 70° or 65° F. An ice-cap devised by Mr. Knowsley Thornton, for applying cold of 32° to the entire head, has been found useful in hyperpyrexia following ovariectomy.

Many substances have the property of reducing febrile temperatures when taken in large doses. Among the most powerful are the complex bodies recently introduced, phenazone, acetanilide, exalgin, and others of the

same class. Their influence on febrile heat is undoubted, and it may be exerted favourably in the early stage of sharp fever from whatever cause, but their continued use is attended with danger. The lowering of the temperature may be dearly purchased at the expense of the patient's strength. Another powerful agent often employed to combat fever is quinine. When given for this purpose, it is administered in doses of from ten to twenty or even thirty grains once in twenty-four or forty-eight hours; or three to six grains of the neutral sulphate may be injected under the skin. Salicylic acid has a remarkable influence on the temperature in acute rheumatism, and some effect, though far less marked, in fever from other causes. It may be added that when pericarditis has come on in rheumatic fever, this drug usually altogether fails to influence the temperature. The only other drug which need be specially mentioned is aconite, the mode of action of which is totally different from that of quinine, and of which it may almost be said that it antagonises the fever process rather than reduces temperature; its most marked influence being on the force of the heart and the contraction of the arteries. The opportunity for the manifestation of its powers occurs in the early stage of catarrhal fever, the result of chill. Given in frequent small doses (a drop or two of the tincture every five minutes till twenty minims or half a drachm has been taken) when the temperature is rising, the pulse frequent and hard, with headache and burning skin, the effects are often striking. When a local inflammation is established, it is no longer of much use; and when the fever is protracted, as in enteric fever, or when there is pneumonia, it may be dangerous, from its depressant influence on the heart. See ANTIPIRETICS.

W. H. BROADBENT.

**FIBRILLATION, Muscular.** — A localised quivering or flickering of muscular fibres. See MOTILITY, Disorders of.

**FIBRINOUS CLOT.**—See CLOT.

**FIBRINOUS CONCRETION.**—See CONCRETION.

**FIBROID DEGENERATION.**—A morbid change which consists in the substitution of a tissue somewhat resembling fibrous tissue for other structural elements; some pathologists consider this change to be of the nature of a degeneration. See DEGENERATION; and CIRRHOSIS.

**FIBROID PHTHISIS.**—A name given to certain cases of phthisis in which a considerable development of fibroid tissue occurs in the lungs. See PHTHISIS.

**FIBROMA.**—A form of tumour composed of fibrous tissue. See TUMOURS.

**FIBRO-PLASTIC GROWTH.**—A form of new-growth, composed of fibro-plastic elements. See TUMOURS.

**FICUS UNGUIUM** (*figus*, a fig; *unguis*, a nail).—A disease of the posterior wall of the nail. See NAILS, Diseases of.

**FIDERIS, in Switzerland.**—Chalybeate waters. See MINERAL WATERS.

**FIFTH NERVE, Diseases of.**—The fifth or trifacial nerve (*nervus trigeminus*), the largest of the cranial nerves, consists of a motor and sensory portion, the sensory fibres passing through the Gasserian ganglion, and being distributed to the face and a portion of the head. The motor portion, much the smaller, is physiologically independent of the ganglion, and supplies the pterygoid, masseter, buccinator, and temporal muscles. The two first divisions—the ophthalmic and superior maxillary—are entirely sensory, and proceed from the ganglion. The third or inferior maxillary division proceeds also from the ganglion, but receives besides the whole of the motor root. Lesions of this nerve cause disorders of sensation, motion, and nutrition or secretion, according to the anatomical position and extent of the injury.

The affections of the fifth nerve may be considered in the following order:—

1. **Trifacial Neuralgia.**—Neuralgia may affect one or all of the three divisions of the nerve. It is fully described under the head of tic-douloureux. See TIC-DOULOUREUX.

2. **Trifacial Anæsthesia.**—Anæsthesia of the trigeminus, usually unilateral, may be dependent either upon (a) *central lesion*; or upon (b) *peripheral lesion*.

(a) *Central lesion.*—Hemiplegia from hæmorrhage, softening from thrombosis, tumour, or other coarse affection of the intracranial nervous system, is usually accompanied by some anæsthesia in the district supplied by the trigeminus, arising probably from interference with the integrity of the fibres of origin of the nerve in their central course. The anæsthesia usually occurs on the same side of the body as the paralysis of motion, and therefore opposite to the seat of lesion. This is always the case when the lesion occupies a position above the pons Varolii. In disease of the pons Varolii, however, the loss of sensibility may involve both halves of the face, although it usually affects the same side as that upon which the limbs are paralysed, and opposite that upon which the portio dura and sixth nerves (when either or both of them are involved) are affected. In cases of apoplexy, the anæsthesia is usually very imperfect, and not sharply defined. It is short-lived, lasting from a few hours to days; but in certain cases it may continue, and even outlive the motor paralysis with which it is conjoined.

Intracranial tumours may produce more persistent anæsthesia, either by immediate destruction of sensory fibres, or, indirectly, by the cerebral enlargement, due to their growth, causing compression of the fifth nerve as it traverses the floor of the skull.

(b) *Peripheral lesion.*—Anæsthesia dependent upon lesion of the trigeminus in its peripheral course is a symptom of serious moment, which it is important to distinguish from that of central origin; and this may be accomplished by noting the following points: The degree of peripheral anæsthesia far exceeds that which obtains in cases owing their origin to a central cause. It is much more complete, and may involve, which the latter does not, trophic and vaso-motor complications. Its extent varies according as the trunk of the nerve, including the Gasserian ganglion, is involved; or only one or two of its branches. Should the main trunk be affected, there is more or less complete anæsthesia of one side of the face and part of the ear, conjunctiva, cornea, nostril, mouth, half the tongue, the gums on the same side, and a part of the palate. If the conjunctiva be touched with the finger, there is no reflex contraction of the eyelids. A glass from which the patient drinks seems to him as though it were broken, for he feels the material on the sound side and not on the affected side. The skin of the face is cool, and may be somewhat œdematous, and purplish in tint. After a few days, if the cause persists, the eye on that side looks dry, glazed, and congested; the cornea becomes cloudy, and in time sloughs and perforates, the contents of the eyeball escaping to a varying extent, so that the organ is destroyed. There is dryness of the nostril on the affected side, and irritant substances applied to it fail to produce sneezing. Taste is lost on that side of the tongue, except at the base, which is supplied by the glossopharyngeal nerve. The salivary secretion is diminished. In time there may be bleeding from the gums and ulceration of the mucous membrane. Should the lesion exist upon one of the three divisions of the trigeminus, the anæsthesia will be found sharply limited to the district supplied by that division.

The nature of the lesion must be determined by the examination of concomitant conditions. It may consist either in caries of the bone, tumour, aneurysm, or meningitis, acute or chronic. Whatever be the active cause by which the nerve is damaged, the effects will be the same: pressure upon, and disorganization of the nerve-fibres will result in the disorders described—sensory, motor, trophic, and vaso-motor. In such circumstances, one or more of the other cranial nerves are usually affected coincidentally. In tubercular meningitis, the fifth nerve is shown to be paralysed (along with others traversing the floor of the skull) by the conjunctivitis and corneitis so

often present in advanced stages of the disease. Should the condition accompany bulbar paralysis, the lesion must be referred to the nuclei of origin of the nerve in the medulla oblongata.

**TREATMENT.**—Syphilitic gummata on the floor of the skull, developed either in the membranes of the brain or in the nerve itself, are so frequently the cause of the disorganization of the fifth nerve which gives rise to anæsthesia, that in all cases it is right—unless some other explanation is evident beyond all doubt—to bear in mind the possibility of such a cause, and to prescribe accordingly without delay. From 10 to 20 grains, or more, of iodide of potassium should be administered every four hours. Should there be a gumma pressing upon the trunk of the nerve, this treatment will probably have the effect of bringing about a rapid amelioration, and, in many cases, supposing it has been applied early enough, a complete cure. It is evident that, as regards other causes, there is no particular indication for treatment, which must be adapted to the special circumstances of the case.

**3. Trifacial Hyperalgesia.**—Hyperalgesia may accompany or precede neuralgia of the fifth nerve. It may also precede facial anæsthesia when this is due to neuritis. There are varieties in the degree of this hyperalgesia. It is sometimes so severe that the slightest touch occasions pain. The face cannot then be washed in the ordinary way, but the patient has to take a piece of sponge or wetted rag and cautiously dab the skin with it. Sometimes it is described as a feeling of soreness only when the hand is passed over the face. In either case the condition is accompanied by diminution of the tactile discrimination in the part. In *mimetic spasm* of the portio dura, there is often hyperalgesia in the region of one or more divisions of the fifth, and the lesion is then doubtless connected with the deep origin of this nerve. In blepharospasm it will often be found, if the face be carefully examined, that pressure with the finger at some point will check the spasm. Subcutaneous division of a twig of the fifth (or afferent nerve) at this point will often bring about a cure of the affection. The supra-orbital or subcutaneous malar are the nerves most commonly in fault.

Photophobia is referable to hyperalgesia of the branches distributed to the conjunctiva.

**4. Motor Disorders.**—Affections of the motor root of the fifth nerve are either (a) of a *spasmodic*; or (b) of a *paralytic* character.

(a) *Spasm.*—Spasm of the muscles supplied by the trigeminal nerve may be tonic or clonic. In trismus, or 'locked jaw,' the teeth are clenched together by the tonic contraction of the masticatory muscles, which can be felt tense to the touch. According as the muscles are involved generally, or only partially, the lower jaw will be fixed in a

symmetrical position, or be pulled over to one side, or advanced or receded. Clonic spasm of the same muscles is observed in various convulsive disorders; and slower movements of a horizontal character constitute the grinding of teeth sometimes indicative of cerebral disease.

Trismus may either be one symptom of tetanus (see TETANUS), or it may occur by itself, and then it either arises from cold, or is of reflex origin, from irritation of the sensory portion of the nerve by decayed teeth, dentition, or disease of the jawbone. It may be due to the presence of a foreign body, possibly of very small size, lodged in the cicatrix of a wound upon the face, or even in some distant part of the body. Irritation from worms is a possible cause. It is still more commonly hysterical.

**TREATMENT.**—When arising from cold, the constant current should be applied to the contracted muscles. Any source of irritation, whether from decayed teeth, or otherwise, must be sought for, and, if possible, removed or remedied.

The removal of a foreign body will sometimes bring about an immediate cure. This failing, the hypodermic injection of morphia, in doses of gr.  $\frac{1}{8}$ , may be employed, and bromide of potassium given internally in doses of 20 grains. When the presence of worms is suspected, appropriate treatment must be employed. If the affection be hysterical, somewhat powerful faradic currents, directed to the muscles of the jaw, will scarcely ever fail to open the mouth and cure the ailment. Hysterical trismus cannot be mistaken for dislocation of the jaw, if it be remembered that in the latter accident the jaw is fixed with the mouth partly open.

(b) *Paralysis.*—Paralysis of the masticatory muscles is not very common, but may be observed sometimes in cases of bulbar paralysis, or it may accompany anaesthesia of the face, and depend upon tumour, abscess, aneurysm, or some such coarse disease encroaching upon the trunk of the nerve within the cranium. To test the state of the muscles, the patient should be asked to move his jaw to and fro laterally, as well as in opening and shutting the mouth. Any irregularity of movement will be evident to the eye, and defective strength or absence of contraction in the affected muscles may be felt by placing a hand on each cheek, whilst the patient performs movements of mastication. When the jaw is found to fail in being carried to one side in a munching movement, the fault of course lies with the pterygoid muscles of the *opposite* side. The affection is more often unilateral than bilateral. Its importance is bound up with that of the lesion which gives rise to it.

As in peripheral affections of the sensory portion of the nerve, especial attention should be paid to the causation, and if this probably

depends upon a tumour, the possibility of its syphilitic character should be borne in mind, and iodide of potassium administered in doses of from 10 to 20 grains, or more. If these measures fail, the question of surgical operation may have to be entertained. See NEURALGIA; and TIC-DOULOUREUX.

T. BUZZARD.

**FILARIA** (*filum*, a thread).—A genus of nematode worms, not very clearly defined, but which contains a variety of thread-like parasites whose body is of uniform thickness throughout, and at least fifty times longer than it is broad. Under this head are often included several human parasites, such as the *Dracunculus*, or Guinea-worm (*Filaria medinensis*), and the lung strongle (*F. bronchialis*), in addition to a variety of larval or sexually immature nematodes, whose genetic relations are only very imperfectly understood. In the latter category may be placed Bristowe and Raimey's entozoon (*F. trachealis*); von Nordmann's eye-worm (*F. oculi-humani* or *F. lentis*); the *loa*, infesting the eyes of the Angola coast and Gaboon negroes (*F. loa*); and, lastly, the nematode hæmatozoon (*F. sanguinis-hominis*) described by the late Dr. Timothy Lewis. It may be doubted if any of the above-mentioned parasites ought to be included in the genus *Filaria*, as understood by modern helminthologists, but, practically, it is still found convenient thus to speak of them. The *Dracunculus* will be found described under ENTOZOA; whilst the microscopic nematode infesting the blood will be found noticed under the articles CHYLURIA, and FILARIA SANGUINIS HOMINIS. T. S. COBOLD.

#### FILARIA SANGUINIS HOMINIS.

This name was applied by Lewis to the embryo filaria which he discovered in human blood in 1872; and so long as no other similar parasite was found to have its habitat in the circulation, the name was appropriate. Recently, however, the writer has pointed out that the blood of certain Africans is liable to be infested by the embryos of two additional species of filaria; it therefore becomes necessary to modify Lewis's original name. Observation has shown that the filaria of Lewis appears in the blood only at night, disappearing from it during the day; whereas, of the two recently discovered species, one of them appears in the blood during the day only, disappearing from it at night; the other, in those individuals in which it occurs, is present in the circulation both during the day and during the night. Taking these facts as a basis for nomenclature, the writer proposes to name the three species—

*Filaria sanguinis hominis diurna.*

*Filaria sanguinis hominis nocturna.*

*Filaria sanguinis hominis perstans.*

*Methods of demonstrating filaria embryos in the blood.*—Blood is obtained in

the usual way from a finger-tip; but in looking for filariæ, the respective habits of the different species must be borne in mind. Thus, if search is to be made for *filaria sanguinis hominis diurna*, the blood should be drawn between the hours of 11 A.M. and 6 P.M.; if for *filaria sanguinis hominis nocturna*, between 9 P.M. and 6 A.M.; if for *filaria sanguinis hominis perstans*, it may be drawn at any hour of the day or night.

To study the movements of the filariæ, ordinary preparations of freshly drawn blood must be used; but to warrant a positive opinion as to the absence or presence of embryos in the circulation, and for purposes of enumeration, a larger quantity of blood than can be dealt with rapidly in the ordinary way must be searched. The following is a good plan. Spread about half a drop of blood on a slide in a uniform layer over an area about 1" by 1", and allow it to dry. The slide may be stained and examined at once, or stored away till such time as may suit the observer's convenience. All that is necessary to demonstrate the filariæ in such slides, no matter how old they are, is to immerse them for two hours in a half-per-cent. solution of eosin, or a weak solution of fuchsin (one drop of the saturated alcoholic solution in an ounce of water), then wash them in one or two waters, and mount in Farrant's solution or glycerine jelly. So prepared, the filariæ and white blood-corpuscles are stained, whilst the colour of the red blood-corpuscles is discharged. To demonstrate the sheath, shape, and structure of the filariæ, make a thin film of blood by applying a clean slide over another slide having a droplet of fresh fluid blood on it; after allowing the blood to spread out between the slides, rapidly glide or pull them apart; immediately invert the slides over a capsule containing a few drops of acetic acid until they are dry; then immerse them in a half-per-cent. solution of eosin for two minutes, wash thoroughly, dry slowly, and mount in balsam. So prepared, the filariæ and leucocytes show pearly-white, whilst the red blood-cells are deeply, and the liquor sanguinis is lightly, stained by the eosin.

No matter how prepared, the slides ought to be scrutinised in the first instance with a very low objective—an inch is sufficient—and every part of them examined. A quick-travelling mechanical stage is of great assistance in this, and ensures thoroughness. When a filaria is found it can be centred and examined with a quarter-inch or higher objective; but it must not be forgotten that, in the first instance, only very low powers are suitable for searching.

The three species of embryo filariæ sanguinis hominis closely resemble each other. As seen in recently drawn blood, they are long, slender, gracefully formed, transparent, colourless, snake-shaped organisms, which

for hours continue in a state of great activity, wriggling and twisting about on the slide like a wounded earth-worm, or an eel on a hook. After a time movement gradually slows down; but by a little management in preventing drying of the slide, the parasites can be kept alive for five or six days. In none of them can anything like an alimentary canal, or any definite internal structure, be made out.

As far as is at present known, the points of contrast in the three species are as follows:—

1. *Filaria sanguinis hominis diurna* (fig. 51).—The free hæmatozoal embryo of a species of filaria, the mature form of which is still unknown. Excepting that it enters the circulation during the day, this blood-worm resembles very closely in size, form, and habit the now familiar *filaria sanguinis hominis nocturna* of Lewis. The peculiarity in periodicity referred to is, doubtless, an adaptation to the habits of its unknown intermediary host. There is some reason for supposing that the filaria loa—a parasite living in the connective tissues, and sometimes showing itself underneath the conjunctiva in negroes—is the mature form of *filaria sanguinis hominis diurna*; for the geographical distribution of both, as far as our knowledge of this extends, is the same, and the undoubted embryo of *filaria loa* resembles *filaria sanguinis hominis diurna* in shape, and possibly in size; and, moreover, a patient of the writer's, who had at one time a filaria loa under his conjunctiva, has now the *filaria sanguinis hominis diurna* in abundance in his blood. The parasite seems to be confined to the tropical zone of Africa, more especially to the west coast. Future observation is likely to show that a large proportion of the inhabitants of these districts are affected with these worms, and it is likely that in a proportion of instances some pathological condition may be traced to them. As yet our information on these points is much too fragmentary to warrant even speculation.

2. *Filaria sanguinis hominis nocturna* (fig. 52).—The free hæmatozoal embryo of *filaria Bancrofti*. We owe the first notice of this parasite to Demarquay, who, in 1863, found numerous specimens of what, considering the circumstances of the case, must have been *filaria sanguinis hominis nocturna*, in the contents of a lymphous tumour of the thigh.<sup>1</sup> Later, in 1869, Wucherer in Bahia, and, quite independently, in 1870, Lewis in Calcutta, found the same parasite in chylous urine. It was not, however, until 1872, when Lewis showed that the normal habitat of this embryo worm was the human blood, that the discovery excited much interest. Since that date the significance of this parasite as a factor in tropical pathology has gradually come to be recognised, and many interesting

<sup>1</sup> *Gaz. Med.* 1863, p. 665.

points of a complicated life-history have been worked out.

In the first issue of this Dictionary Lewis described the *filaria sanguinis hominis nocturna* as follows: 'Its average length is  $\frac{1}{75}$ " (= 0.34 mm.); its breadth  $\frac{1}{3500}$ " (= 0.007 mm.), or about equal to the diameter of a red blood-corpuscle. It is enclosed in a transparent tubular sac, within which it can be seen to alternately contract and elongate itself. This sac is extremely delicate and translucent, and may sometimes, when the worm has shortened

itself more than usual, be seen collapsed and folded like a ribbon, and the next moment be instantaneously straightened again, by the extension of the filaria to its ordinary length. After death the worm may occupy either the entire length of the tubular sac, or be so contracted as to leave the tube empty at one or both ends, as may be observed in the woodcut (fig. 54).'

As no sign of growth or of reproductive organs is distinguishable in this the hæmatozoal stage of the parasite, it is evident—and

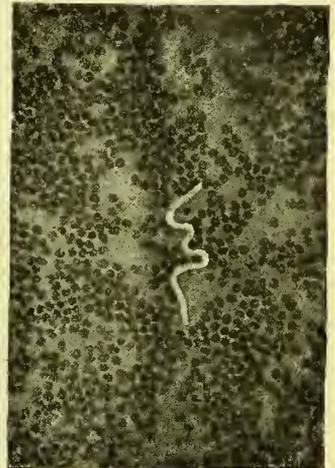

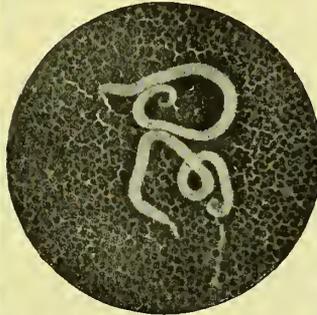

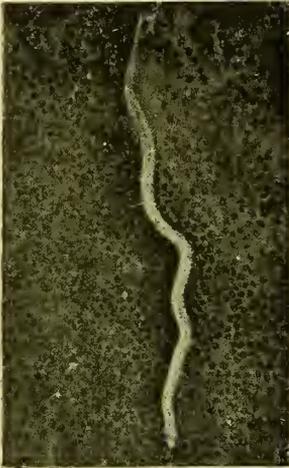

FIG. 52 — *Filaria sanguinis hominis nocturna* × 180.—1. Measures  $\frac{1}{80}$  in. by  $\frac{1}{3500}$  in., or thereabouts. 2. Is provided with a coarser sheath. 3. Caudal end tapers gradually for about one-fifth of the entire length of the animal, and terminates in a sharp, or nearly sharp, point. 4. Cephalic end is rounded off, and has obscure oral movements of a pouting character. 5. No tongue-like organ visible. 6. Appears in the blood at night, disappearing during the day. 7. Has a wriggling, but no locomotive, movement. 8. Many specimens have a well-marked granular-looking aggregation about the middle of the body.

FIG. 51. — *Filaria sanguinis hominis nocturna* × 180 (this fig. and figs. 52 and 53 from microphotographs by C. Detmold).—1. Measures  $\frac{1}{80}$  in. by  $\frac{1}{3500}$  in., or thereabouts. 2. Is provided with a very delicate sheath. 3. Caudal end tapers gradually for about one-fifth of the entire length of the animal, and terminates in a sharp, or nearly sharp, point. 4. Cephalic end is rounded off, and has distinct oral movements of a pouting character. 5. No tongue-like organ visible. 6. Appears in the blood during the day, disappearing during the night. 7. Has a wriggling, but no locomotive, movement. 8. A few specimens have a faintly marked granular-looking aggregation about the middle of the body, but in none is it very well marked.

FIG. 53. — *Filaria sanguinis hominis nocturna* × 180.—1. Measures  $\frac{1}{125}$  in. by  $\frac{1}{5500}$  in., or thereabouts. 2. Has no sheath. 3. Caudal end tapers more gradually for two-thirds of the entire length of the animal, and is abruptly truncated where it has tapered to about one-third of the diameter of the thickest part of the body. 4. Cephalic end is either conical or truncated, passing from one form to the other rapidly by a peculiar jerking, extruding and retracting, movement. 5. From time to time, a minute tongue-like organ is rapidly protruded and withdrawn at the extremity of the cephalic end. 6. Observes no periodicity. 7. Has a locomotive as well as a wriggling movement. 8. No granular appearance.

this was early recognised—that these blood-worms are only the immature young of parasites which must exist in a sexually mature form elsewhere in the tissues of the human host, and in intimate relationship with the circulation. Lewis made diligent search for the parental form soon after his discovery of the embryo, but it was not until 1877 that he found two living specimens—a male and a female—in the diseased tissues of a nævoid elephantiasis of the scrotum. Late in the previous year Bancroft, in Brisbane, found

several mature females in a 'lymphatic abscess' of the arm, and also in 'an encysted hydrocele of the cord.' The latter were carefully examined by Cobbold, and the parasite was named by him *filaria Bancrofti*. Since that time the mature filaria Bancrofti has been found in India, China, and Brazil. It is a long, thread-like worm, about the thickness of a horse-hair, of a white colour and firm consistence, and exhibits considerable activity, and a remarkable tendency to coil. Cobbold described the female as follows:

'Body capillary, smooth, uniform in thickness. Head with a simple circular mouth, destitute of papillæ (fig. 55). Neck narrow,

FIG. 54.—*Filaria sanguinis hominis nocturna*.  $\times 300$ . (Traced from a micro-photograph.)

FIG. 55.—Anterior end of mature *filaria sanguinis hominis nocturna*.—Mature form.  $\times 100$  diameters.

about one-third of the width of the body. Tail of female simple, bluntly pointed; reproductive outlet close to the head; anus

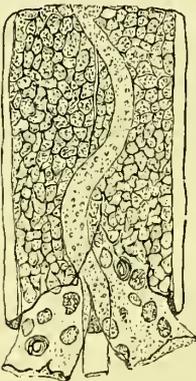

FIG. 56.—A portion of the mature *filaria sanguinis hominis nocturna*, showing uterine tubules filled with ova in various stages of development; also the intestinal tube.  $\times 100$  diameters.

immediately above the tip of the tail. Length of largest females  $3\frac{1}{2}$  in., breadth  $\frac{1}{90}$ '''. In the female the uterine tubes are packed with ova in all stages of development (figs. 56 and

57). Lewis gives the measurement of these, in which the embryos are distinctly visible, as  $\frac{1}{66}$ '' by  $\frac{1}{90}$ '''. In a fresh specimen of the filaria examined by the writer the largest ova gave slightly greater measurements, and

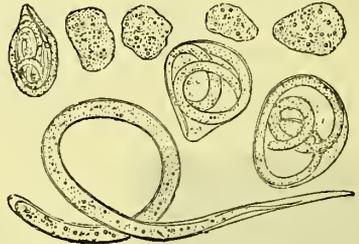

FIG. 57.—Ova and embryos of *filaria sanguinis hominis nocturna*.  $\times 300$  diameters.

he saw that towards the vaginal end of the uterine horns the embryos lay outstretched, and that in the vagina they had very much the appearance they have in the blood, proving that under normal circumstances the parasite is viviparous. Lewis gives the breadth of the fragment of a male he examined as  $\frac{1}{180}$ ''.

It is now known that the parent worms live together in the lymphatics; that the embryo while *in utero*, by dint of vigorous movements, stretches its chorionic envelope to form the long tubular sheath in which it lies extended, as we see it in the blood and lymph, and that, after this stretching of the chorion is complete, the embryo is born into the lymph-stream, which carries it through the glands, along the thoracic duct, and thus into the blood. Under ordinary circumstances of health and habit the hæmatozoon cannot be found in the blood during the day, but at evening it appears there. At first only a very few can be found; as night advances their numbers gradually increase; about midnight they attain their maximum—in some cases as many as 200 may be found in a single drop—after this they gradually diminish up to about 8 or 9 A.M., when they disappear for the day. An attack of fever may disturb this periodicity, and Dr. Stephen Mackenzie<sup>1</sup> has shown—and his observations have been abundantly confirmed—that by causing the subject of filaria infection to sleep during the day and keep awake during the night, the habit of the embryo parasite in his blood is correspondingly changed: it then appears, contrary to its normal habit, in the blood during the day, and disappears from it at night. See NEGRO LETHARGY.

This singular periodicity is, apparently, an adaptation to the nocturnal habits of the female of a particular species of mosquito, which imbibes with the blood the young filaria, and acts as its intermediary host.

<sup>1</sup> *Trans. Path. Soc.* 1882, vol. xxxiii.

Transferred to the stomach of the mosquito, the filaria first casts its chorionic envelope, and then bores its way into the thorax and thoracic muscles of the insect. Here it undergoes a remarkable metamorphosis, eventuating in its becoming possessed of an alimentary canal, a circumcaudal circle of papillæ, and greatly increased size, power, and activity. This metamorphosis takes about six days to complete. At the end of this time the mosquito dies, after depositing her eggs on the surface of the water to which she resorts for this purpose. It is presumed that the filaria then escapes from the body of the insect to the water, into which the latter has probably fallen. Through this medium, it is believed, it gains access to the human body, being swallowed in drinking-water.<sup>1</sup>

**GEOGRAPHICAL DISTRIBUTION.**—The filaria sanguinis hominis nocturna has been found in most tropical and subtropical countries in which it has been properly looked for. Its exact geographical distribution as an endemic parasite is doubtless in keeping with the geographical distribution of the particular species of mosquito subserving its interests as intermediary host; but, as the filaria may live for many years in the tissues of its human host, it is frequently brought by travellers from tropical and other countries to colder latitudes; and there is at least one well-authenticated instance in which it was found in a patient who had never quitted England.

**PATHOLOGICAL RELATIONS.**—Chyluria, œvoid elephantiasis or lymph-scrotum, chylous dropsy of the tunica vaginalis (variously termed chylocele, lymphocele, galactocele), varicose and indurated inguinal glands, chylous ascites, recurring orchitis, certain kinds of abscess occurring in the limbs—especially in the thighs and groins, lymphangitis, and lymphatic fever, are almost invariably accompanied or preceded by the presence of the filaria in the blood or in the lymph, or in both. The association is so constant and so intimate, that in 99 cases out of 100 these diseases may be confidently attributed to the filaria, at all events when they are of tropical origin.

Tropical elephantiasis arabum is also attributed to the filaria, although the parasite is by no means always found in the fully developed cases. Theoretically, all elephantoid diseases are produced by some mechanical or other physical influence operating by obstructing or irritating the lymphatic vessels. In tropical elephantiasis it is maintained that this influence is the filaria nocturna; and on the following grounds. Cases are on record of lymph-scrotum—a disease certainly

attributable to the filaria—passing into true elephantiasis arabum; many cases of true elephantiasis arabum scroti have a history of antecedent lymph-scrotum; lymph-scrotum has supervened in flaps left after removal of an elephantiasis scroti by operation; elephantiasis of the leg has followed on the removal of a lymph-scrotum; lymph-scrotum and elephantiasis of the leg sometimes co-exist in the same individual; a case is on record of lymphorrhagia in an elephantoid leg co-existing with varicose inguinal glands and filariæ, and in which chyluria subsequently developed; an instance is recorded in which a son developed a lymph-scrotum, and the mother—living in the same house—an elephantiasis of the leg; where elephantiasis is endemic, there too chyluria and lymph-scrotum are found. It is unreasonable to suppose that the combinations and concurrences mentioned were, in every instance, simply coincidences; much more likely the same cause produced them all. This being proved to be the filaria in chyluria, lymph-scrotum, and varicose inguinal glands, it follows that it must be the filaria also that produces true tropical elephantiasis arabum. Furthermore, as far as known, the geographical distribution of elephantiasis is co-extensive with that of the filaria.

Because the filaria is not always found in elephantiasis, it has been maintained by some that this parasite cannot be the cause of this disease. The fact is, the filaria is mortal and may die before its host; nevertheless, the ill it has wrought may not disappear at its death. It sometimes happens that in chyluria and in lymph-scrotum no filariæ can be found in the blood, urine, or lymph, although at one period they must have been present; sometimes it can be found in the lymph only, and not in the blood; and instances are on record in which the parasite disappeared from the blood and lymphous discharges whilst the cases were under observation, yet the characteristic morbid discharges persisted. In pathology, as in other things, a transient influence may produce a permanent lesion. It must be admitted, however, that the reason of the very frequent absence of the embryos of the filaria from the blood in developed elephantiasis is not known, and further observations bearing on this point are much wanted.

From the fact that in many countries where the filaria is endemic quite 10 per cent. of the adult population harbour it, yet only a small proportion have any of the diseases enumerated, it is evident that the parasite does not necessarily give rise to disease. It would appear that so long as the parasite is healthy and normally situated it is innocuous. Should it die, it may act as a foreign body and cause abscess; the dead filaria has actually been found in lymphatic abscesses. But the precise way in which the

<sup>1</sup> For a detailed description of the metamorphosis of the filaria in the mosquito, see *Trans. Linnæan Soc. of London*, vol. ii. part 10; 2nd ser. 'Zoology,' April 1884.

parasite usually brings about pathological obstruction of the lymphatics is, as yet, to some extent a matter of conjecture. Of two ways in which it so acts there is good evidence. (1) The parent worm may cause lymphatic stasis by operating at a point high up the thoracic duct, either itself plugging that vessel, or giving rise to inflammatory thickening in or around its walls, ending in stricture. (2) As mentioned, there are instances on record in which, though the filaria was present in the chylous urine, or in the lymph drawn from a lymph-scrutum, or from varicose inguinal glands—yet, after the most careful and prolonged search, it could not be discovered in the blood. It is evident that in these cases there must have been complete obstruction of a lymphatic area, otherwise the filaria embryos must have appeared in the blood, as in ordinary examples of filarial infection. The obstruction could not possibly have been in the thoracic duct, for, if complete in this situation, it must have speedily brought about the death of the patient. It is safe, therefore, to infer that it must have been somewhere on the distal side of the receptaculum chyli. In two such cases the ova of the parasite have been found in the lymph; and it is believed that in this circumstance we have the explanation of the site and character of the lymphatic obstruction in a large proportion of cases. Normally, the parasite is viviparous, and the long, slender, active embryo has no difficulty in finding its way along the lymphatics and through the glands into the circulation. But should the embryo be born prematurely, as in the two cases referred to, before the chorionic envelope has undergone the stretching process already described—that is, should ova (seven or eight times the diameter of the outstretched young) be prematurely launched into the lymph-stream, they act as emboli, and, being very numerous, effectually plug the glands connected, directly or by anastomosis, with the lymphatic vessel in which the aborting parent lies. The location of the worm; the degree of obstruction, whether caused by embolism, pressure, or stricture; pressure by enlarged glands interfering with the compensating drainage of the affected areas by the veins; traumatic irritation of the congested lymphatic area; the position of the part involved as regards dependence or elevation, a most important factor in elephantiasis; the health of the patient; and other circumstances, easily understood, will determine the site and exact character of the resulting disease.

**TREATMENT.**—(a) *Curative.*—No means of killing the filaria have been discovered. The indications for treatment, when disease has developed, are supplied by the pathology. Rest, elevation of the affected parts, elastic bandaging, and other means to facilitate the flow of lymph through the damaged lymph-

atics, are of great benefit. See CHYLURIA; and ELEPHANTIASIS ARABUM.

(b) *Preventive.*—The fact that the mosquito acts as intermediary host indicates the direction that preventive measures should take. Drinking-water, in districts where the filaria is endemic, ought to be boiled and filtered; wells, cisterns, and receptacles for drinking-water ought to be covered with fine wire-gauze, to prevent the access of the mosquito; and persons known to harbour the parasite ought to sleep under properly constructed mosquito-curtains. By any or all of these means this parasite, in the course of a single generation, could be exterminated, and the diseases it produces made things of the past.

3. *Filaria sanguinis hominis perstans* (fig. 53).—The free hæmatozoal embryo of a species of nematode, the mature form of which is unknown. Hitherto this hæmatozoon has been found only in the blood of negroes from the West Coast of Africa, and it is probable that as an endemic cause it is restricted to this part of the world. Twice it has been found in company with the filaria sanguinis hominis diurna; in several other cases it was not so associated. We may therefore infer that the association of filaria perstans and filaria diurna in the two instances referred to was merely accidental.

Attention to the points of contrast between filaria perstans and the other blood-worms, as set forth in the table in page 697, will lead to its recognition. In addition to what has been stated in this table, it may be mentioned that the body of this parasite is possessed in a high degree of powers of elongation and contraction, and that the measurements given in the table referred to are those of the animal when it is dead or moribund. When travelling actively among the blood-corpuscles it sometimes so extends itself as to appear a mere thread, the elongation concurring with a corresponding attenuation; at other times, and when not actively travelling, it assumes the proportions given. A very striking habit which it has is that of coiling itself up like a rope, and remaining motionless in this attitude for a few seconds before resuming its usual movements. Another peculiarity worth mentioning is the result, apparently, of the locomotive habits of this parasite: not infrequently it is seen fixed to one spot on the slide, vainly endeavouring to break away, and constricted by a delicate rope of fibrin. It would seem that in moving about the slide it pushes the strings of fibrin in front of it, and at times becomes entangled in a rope of them.

The filaria sanguinis hominis perstans is probably very common in the endemic region; for, of ten negroes from the West Coast of Africa whose blood was searched, it was found in five.

That in certain cases it gives rise to pathological conditions is probable; but of what

these are we are as yet ignorant. In one case the parasite was associated with the peculiar disease called Negro Lethargy or the Sleeping Sickness of the Congo; in another with insanity; but in the other three instances in which it was found there was no concomitant disease. There may be some grounds for associating it with a peculiar African disease called *Craw-craw*, a kind of itch, apparently induced by a filaria-like parasite, and not the *acarus scabiei*; as yet this supposition is little more than hypothetical.

The presence of a beak, the absence of a sheath, the marked locomotor habits, the extensibility and pliancy of its body, and also the non-observance of any periodicity in its entrances and exits from the circulation, suggest that the embryo *filaria sanguinis hominis* perstans gains its freedom and enters its particular intermediary host by dint of its own efforts, and that it is not, as is the case with *filaria sanguinis hominis nocturna*, and probably *diurna*, dependent on the good offices of some species of mosquito or other bloodsucker.

PATRICK MANSON.

**FISSURE** (*findo*, I cleave).—A narrow and superficial crack or solution of continuity, observed on the skin and mucous membranes, and especially near the line of junction of these structures, as on the lips and within the anus. See ANUS, Diseases of; and CHAPS.

**FISTULA** (*fistula*, a pipe).—A narrow track or canal leading from a free surface, and extending more or less deeply to some seat of local irritation; or it may be constituting an abnormal communication between two or more cavities, as in the case of vesico-vaginal or recto-vaginal fistula. See ABSCESS.

**FISTULA IN ANO**.—See RECTUM, Diseases of.

**FIT**.—A popular synonym for a sudden seizure characterised by loss or disturbance of consciousness from any cause, with or without convulsions (see CONVULSIONS; EPILEPSY; HYSTERIA; and SYNCOPE). The term is also applied to a sudden or acute seizure of certain diseases, such as gout, asthma, and ague.

**FLATULENCE** (*flatus*, a puff of wind). SYN.: Fr. *Flatulence*; Ger. *Flatulenz*.

**DEFINITION**.—The undue generation of gases in the stomach and intestines.

**ÆTIOLGY**.—The principal cause of flatulence is fermentation or decomposition of the contents of the stomach and bowels—a condition usually induced by embarrassment of function. Hence it is a common symptom in dyspepsia—especially the atonic forms as met with in the debilitated and the aged, constipation, gastritis, enteritis, hepatic disorders, and intestinal obstruction. When flatus is generated too rapidly to be accounted

for by fermentation, as in hysteria, hypochondriasis, and other forms of nervous debility, it has been ascribed to secretion of gases from the mucous membrane.

**SYMPTOMS**.—The clinical phenomena vary as flatus is retained or discharged; and with the seat of its formation, whether chiefly in the stomach or intestines. In the former the concomitant symptoms are those of dyspepsia; in the latter there is usually constipation. As a rule, however, flatulence pervades at the same time more or less all the hollow viscera, and indicates torpor of the digestive organs. It is apt to lead to these further evils:—*(a) Pain* from distension or from irregular and forcible contractions of the walls—hence gastrodynia and colic are apt to arise; *(b) arrest of the normal movements* of the stomach and intestines, and consequent accumulation within them of fermentable matters, with further generation of gases, leading to paralytic distension: hence dilatation of the stomach and colon, tympanites or meteorism, and aggravation of pre-existing dyspepsia or constipation may ensue; and *(c) pressure on adjacent organs*, such as the heart and lungs, inducing palpitation and irregular action of the heart, precordial anxiety, faintness, vertigo, dyspnoea, or even asphyxia.

In tympanites there is a rapid generation of flatus, which overpowers the contractility of the hollow viscera; and the abdomen is round, tense, and tympanitic. See TYMPANITES.

**TREATMENT**.—*(a) Imprisoned flatus should be dislodged* by friction of the abdomen with stimulating liniments, and gentle kneading of the most distended parts; large draughts of hot water; spirit and hot water; ammonia, ether, or spirit of chloroform; aromatic stimulants—ginger, capsicum, cloves, mint, anise, cajuput, camphor, or cascarrilla. When flatulence is chiefly intestinal, enemata containing laudanum with asafetida, turpentine, or rue; and the compound asafetida pill with extract of nux vomica, and an aperient, are the most useful measures.

*(b) The generation of flatus should be arrested*. Fermentation may be checked by sulphite or sulpho-carbolate of sodium, sulphurous acid, carbolic acid, creasote, terebene, salol, or charcoal—from the poplar or vegetable ivory, immediately after food; and by correcting and toning the digestive organs. Repeated fractional doses of calomel will also frequently arrest fermentative flatulence. Food likely to ferment or lodge, such as starch, sugar, fruits or green vegetables, and warm liquids—especially tea and soups—should be avoided; the meals should be well masticated and solid throughout, and liquids should only be taken sparingly at the close or an hour after. In some cases, however, flatulence is connected with an insufficient supply of fluids, and should be met by

increasing it; then also a tumblingful of hot water night and morning and an hour before each meal, which should consist of solids, may prove useful. Alkalis—carbonate of magnesium and bicarbonate of sodium—and bitters, especially strychnine, are often useful in the flatulence of hysteria, hypochondriasis, of the very nervous and the aged; but perhaps the best results follow alkalis with nux vomica and bismuth an hour before, and hydrochloric acid alone or with some reliable preparation of pepsin after food. It is also essential to see that the action of the liver is healthy.

GEORGE OLIVER.

**FLEXION** (*flecto*, I bend).—A bending. This term is applied either to the act of more or less forcible flexion, as in some methods of treatment, for example in the cure of aneurysm or the reduction of dislocations; or to the condition in which parts are bent, as the result of disease or of disorder, as when the limbs or certain internal organs are bent upon themselves. See WOMB, Diseases of.

**FLINSBERG, in Silesia.**—Chalybeate waters. See MINERAL WATERS.

**FLOODING.**—A popular term for excessive discharge of blood from the womb. See MENSTRUATION, Disorders of; and PREGNANCY, Disorders of.

**FLUCTUATION** (*fluctus*, a wave).—A physical sign consisting in a wave-like or undulating sensation. It is elicited by a peculiar mode of palpation with the one hand, while percussion is made with the fingers of the other; and is due to the presence of a fluid in a natural cavity, such as the peritoneum, or in an abnormal closed space such as a cyst (see PHYSICAL EXAMINATION). The term 'fluctuation' as used by the surgeon has a somewhat different signification, being applied to the sensation of the presence of a fluid which may be felt when alternate pressure with the fingers is made, as over the seat of an abscess. See ABSCESS.

**FLUKE.**—See ENTOZOA.

**FLUOR** }  
**FLUX** }.—A flow or excessive discharge from a mucous surface, through any of the natural passages, of serum, blood, mucus, pus, or the various secretions. As illustrations of fluxes may be mentioned salivation, bronchorrhœa, biliary flux, diarrhœa, dysentery or bloody flux, cholera, and leucorrhœa or white flux (*fluor albus*).

**FŒTUS, Diseases of the.**—Two classes of abnormal conditions are seen in the fœtus, namely: Those which depend upon some interference with the process of development, such as malformations and monstrosities; and those which are the result

of disease. This article treats of the latter only.

1. *Amputation.*—Amputation, partial or complete, of fœtal limbs may take place, from constriction of the limb by a band of the amnion. An attempt at reproduction of the lost limb is sometimes seen, in the shape of rudimentary fingers and toes, projecting from the stump. That such a stump is the result of amputation is proved by the fact that the part cut off has been found *in utero*.

2. *Spontaneous fractures and dislocations.* Fractures and dislocations occur *in utero*, the latter being the more rare. They are due to some condition of the bones and ligaments respectively, leading to undue fragility of those structures; for they are always multiple, and are not accompanied with bruising of the adjacent soft parts.

3. *Tumours.*—New-growths are met with in the fœtus—cysts of various kinds, fibroma, lipoma, &c. That most special to the fœtus is a tumour situated over the coccyx, which may be as large as a fetal head. Such tumours are spheroidal or ovoidal in shape, elastic in consistence, and present rounded inequalities on the surface. On section they are found to consist of strong fibrous trabeculae, in the meshes of which are numerous small cysts lined with epithelium. It is thought by many that they originate in Luschka's gland. Another special kind of tumour is that known as a *fœtal inclusion*—a swelling usually on the lower part of the trunk, and containing some part of another fœtus, more or less imperfectly developed.

4. *Inflammation of serous membranes.* This form of disease may occur in the fœtus, such as pleurisy and peritonitis. The morbid anatomy of these changes does not differ from that in the adult. Peritonitis is often found associated with syphilis; and it appears to be almost always fatal to the fœtus.

5. *Visceral inflammations.*—Inflammation of the lungs has been met with, in the form of grey or white lobular hepatisation. It is most frequent in syphilis. Enteritis has also been described. Certain malformations of the heart which are met with can be explained by supposing the occurrence of endocarditis during fœtal life; but there is no proof that the fœtus is subject to rheumatism.

6. *Specific fevers.*—The morbid changes of *enteric fever* have been found in the fœtus. In pregnant women suffering from *intermittent fever*, paroxysms of convulsive movements of the child have been felt to occur as regularly as the attacks of ague in the mother; and the child when born has been found to have a large spleen. Children have also been born with skin-eruptions thought to resemble those of *measles*, *scarlatina*, and *small-pox*. The facts as to the last-named disease are the most numerous and probable. The eruption of variola in the fœtus differs some-

what from that seen after birth, because, the skin of the fœtus being bathed with fluid, no crusts form, and the pustules run a course like those on mucous membranes.

7. *Diseases of the skin.*—The fœtus is subject to skin-diseases. Pustules of ecthyma; patches of erythematous redness; ulceration of the skin, and syphilitic eruptions, have been seen. Intra-uterine ichthyosis is met with. Children have been born jaundiced, but only by mothers themselves suffering from that condition. But women with jaundice do not always bear jaundiced children. Jaundice is not necessarily fatal to the fœtus.

8. *Syphilis.*—Syphilis leads to various lesions in the fœtus; and while it usually proves fatal, the subjects of it that may survive till birth are feeble and badly nourished. Flat tubercles occur on different parts of the skin, especially round the mucous orifices; and pemphigus may be seen, affecting chiefly the palms of the hands and the soles of the feet. The occurrence of peritonitis has already been mentioned. Yellow indurated nodules, of varying size and number, may be found in the liver, as well as in the lungs. A peculiar change has been described in the thymus gland, in which this structure externally appears healthy, but when cut into and compressed exudes a whitish puriform fluid. Other changes have been recorded, affecting the spleen, pancreas, and suprarenal capsules, but they are not distinctive. Changes in the bones have also been described, consisting of an osteochondritis, affecting the ends of the long bones, most frequently the lower end of the femur.

9. *Rachitis.*—Fœtal rickets is a disease somewhat different from that seen after birth. The limbs are short, very fat, the fat being thrown into rolls separated by transverse constrictions; the trunk, especially the abdomen, is large; the head often hydrocephalic. The bones are short, often fractured and bent; there is swelling, softening, and delayed ossification of the epiphyses. It may begin early, and cease before delivery; or the child may be born with the disease in progress. Nothing is known of its causes.

10. *Tuberculosis.*—Tuberculosis sometimes commences in the fœtus, tubercles having been found in the mesentery and in the lungs.

11. *Dropsies.*—Dropsy is met with in the fetus, sometimes of the serous cavities, of which hydrocephalus is the most common. It is often associated with rickets. Next in frequency comes ascites; and lastly hydrothorax, which is very rare. These affections may destroy fetal life *in utero*; but they more often lead to death because they render destructive operations necessary before delivery can be accomplished. General anasarca is also met with, and there is reason to believe that it depends upon disease of the

placenta, impairing the excretory function of that organ. It is always fatal, if not before birth, within a few hours after it.

12. *Visceral diseases.*—Hypertrophy of the liver, spleen, or kidneys may occur in the fetus. Cystic disease of the kidneys may be met with, the organs being converted into a mass of cysts containing no trace of secreting structure. Both kidneys are usually affected, and the disease is generally associated with some malformation elsewhere. Hydronephrosis, single or double, along with dilatation of the ureter, or ureters and bladder, has been seen, dependent upon impermeability of some part of the urinary passages. Any of these visceral diseases may form a tumour so large as to impede delivery. None of them can be diagnosed before birth. Concretions of uric acid and urates are not uncommon.

#### The Causes of Death of the Fœtus.

The various causes of death of the fœtus *in utero* may now be briefly considered. The first of these is *injury*, as when the mother receives a blow upon the abdomen, or has a fall. Such occurrences rarely injure the fœtus directly, although this has been known to happen. When they prove fatal to the fetus, they do so by leading to hæmorrhage into, or separation of, a portion of placenta, and consequent disturbance of the fetal circulation. *Poisons* in the mother's blood, such as lead, urea, bile, or carbonic acid (as in the case of heart-disease with cyanosis), may lead to death of the fœtus. *Syphilis* has already been referred to. *Epileptiform convulsions* may destroy fetal life, either by asphyxia, or by leading to hæmorrhage into the placenta. Extreme *anæmia* and the *cancerous cachexia* are among the causes of fetal death. Any kind of disease attended with *pyrexia* will also destroy fetal life if the temperature rise high enough. A temperature exceeding 105° F. appears to be invariably fatal to the fœtus. Certain *diseases of its appendages* may lead to death of the fœtus, such as hæmorrhages into the placenta, old organised clots forming what are called placental 'infarcts'; obliteration of the umbilical vessels; or interruption of the circulation in the cord by knots in it, or pressure upon it. It is believed that there are some *diseases of the mother's uterus* which lead to death of the fœtus; but what they are is not known. It is said that some women acquire a habit of having dead children. This means that there are cases in which an apparently healthy woman will repeatedly have dead children, the cause of whose death a skilled observer cannot find out. In other words, there are causes of fœtal death as yet unknown.

**The Consequences of Death of the Fœtus.**—A dead fœtus while retained *in utero*, and thus protected from the air, does not putrefy, but undergoes a process of

maceration. The whole body becomes soft and flaccid, its tissues being infiltrated with fluid; but it has no putrid odour. The skin presents bullæ filled with reddish serum, and the epidermis is readily detached with slight friction. The surface is of a cyanotic colour, which after exposure to the air becomes of a more or less bright red; it is not greenish as is seen in putrefaction. The cellular tissue is infiltrated with bloody serum. The viscera have lost their distinctive tints, and become of a reddish-brown colour. The cranial bones are abnormally mobile, overlapping one another to a greater extent than normal; and the periosteum may be stripped off them. These appearances are much the same, whatever be the cause of death, but they vary in degree according to the length of time which has elapsed since death.

Besides the diseases of the fœtus described above, there are others which are not fatal, and the chief interest of which lies in their course and treatment after birth. These are discussed in other articles, and need not be mentioned here. G. E. HERMAN.

**FOLIE CIRCULAIRE** (Fr.)—This term is applied by the French psychological physicians to a variety of insanity characterised by alternations of excitement and depression. The patient passes through an attack of mania of perhaps an ordinary character, but when he appears to have recovered he sinks into melancholia, and thence emerges again to become maniacal and excited. The duration of each stage may vary from weeks to months. Sometimes one state will follow the other immediately; in other cases a period of convalescence will intervene, during which the patient appears well, and can hardly be considered insane. Yet the prognosis is extremely unfavourable in all such cases; and it is of great importance in estimating the extent of recovery of a patient, that it should be clearly ascertained that the attack is not one of a series following one another in the manner mentioned.

G. F. BLANDFORD.

**FOLLICLES, Diseases of** (*folliculus*, dim. of *follics*, a bag).—The name 'follicle' has been applied to a great variety of different structures, which have in common the shape of a bag or sac, whether circular or elongated in outline; for example, the Graafian follicles, the lymphatic (Peyerian) follicles of the intestine, and the follicles of the mucous membrane of the stomach, intestine, and uterus. The name has been further extended to include glands somewhat more complex in structure, such as the sudoriparous glands or sweat-follicles, the sebaceous follicles, and the tonsils; as well as the saccular depressions in which the hair and the teeth take their origin. The name *synovial follicles* is sometimes given to processes of synovial

membrane invaginated in the capsule of a joint.

For an account of the diseases of these various structures, the reader is referred to the several articles under which they are discussed; but so far as the true follicles are concerned, the following may be said to be the principal morbid changes to which they are liable: atrophy; hypertrophy; obstruction, and distension; inflammation; ulceration; cystic disease; new-growths; tubercle; acute specific processes, such as the typhoid; and parasitic disease.

**FOMENTATION** (*foveo*, I keep warm).

SYNON.: Fr. *Fomentation*; Ger. *Bähung*.

DEFINITION.—Fomentation is the application to the surface of the body of flannels, cloths, or sponges moistened with hot water, either pure or containing some medicinal substance in solution.

ACTION.—The action of a simple fomentation is the same as that of a poultice. By its warmth and moisture it tends to relax the muscular fibres of the skin and soften the cuticle, thus relieving tension, and diminishing pain and irritation. In the early stages of inflammation it favours resolution, by maintaining the temperature, and promoting active circulation through the area which has suffered from the injurious influence which has started the process. In the later stages it promotes and hastens suppuration, by causing dilatation of the vessels, and encouraging exudation. A fomentation is superior to a poultice in lightness and cleanliness, but unless care be taken it loses its heat more quickly. This disadvantage may be overcome by covering the fomentation with a thick layer of cotton-wool.

APPLICATION AND USES.—A fomentation is thus applied: A piece of coarse flannel, sufficiently large to cover the affected part when folded into two layers, is put into a basin, and boiling water is poured upon it. It is then lifted from the basin with a pair of tongs or some convenient instrument, and dropped on the wringer. This is a stout piece of towelling with a stick attached to each end. The sticks then being twisted in opposite directions, as much water as possible is squeezed out of the flannel. It is then immediately placed on the affected part, and covered with a large piece of oiled silk or indiarubber sheet extending at least one inch on each side of it. Over this may be placed a thick layer of cotton-wool, and a bandage. If the flannel be not squeezed sufficiently dry, it will wet the bed or clothing. If not sufficiently covered with oiled silk and wool, it soon becomes cold. Whatever means may be taken to retain the heat of a fomentation, it can be kept above the temperature of the body only for a few minutes. If, therefore, the full effect of fomentation is desired to be obtained, the flannels must be changed every

twenty minutes. In many parts a sponge, or a piece of spongio-piline, wrung out of boiling water, forms a most convenient form of fomentation. When the fore-arm or hand is affected, a bath of hot water may be substituted for fomentations. The temperature of the water must be maintained by the repeated addition of small quantities of boiling water.

Fomentations are especially useful in all cases of erysipelas and diffuse cellulitis, and in boils. In peritonitis they are borne more easily than poultices, on account of their greater lightness. Whenever they can be employed they are superior to poultices, on account of their cleanliness. They are not applicable to cases in which there is a discharging wound or abscess, as under such conditions the cloths become foul.

**VARIETIES.**—If it is desired to add some slight counter-irritation to the warmth and moisture, the fomentation may be sprinkled with turpentine before it is applied. This forms the ordinary *turpentine-stupe*. The sedative action of the fomentation may be increased by sprinkling it with laudanum. The ordinary poppy-fomentation is often used with the same intention. It is thus prepared: Half a pound of poppy-heads with the seeds taken out is boiled for ten minutes in four pints of water, and the liquid then strained off. The decoction is kept warm over a fire, and the flannels dipped in it and applied as before described about every half-hour. The term 'dry fomentation' is sometimes applied to bags of hot salt, bran, or chamomile-flowers; or pieces of flannel toasted before a fire and laid on hot. These often give relief in cases of intestinal, renal, or biliary colic.

MARCUS BECK.

**FOMITES** (*fomes*, touch-wood, tinder).—Substances capable of retaining contagium-particulae, and thus of being the means of propagating any infectious disease. The most important fomites are bed-clothes, bedding, woollen garments, carpets, curtains, and letters. See **CONTAGION**.

**FOOD.**—See **ALIMENT**; and **DIET**.

**FOOD, Ætiology of.**—See **DISEASE**, Causes of; and **DIGESTION**, Disorders of.

**FORAMEN OVALE, Patency of.**—See **HEART**, Malformations of.

**FORCIBLE FEEDING.**—In the treatment of insanity, and sometimes under other circumstances, it happens that we are compelled to administer food by force to patients who, for one reason or another, refuse to take it. The majority of these persons are melancholics who think they ought not to eat, or try to commit suicide by starvation, and many are in a feeble bodily

condition when they commence this refusal. Such persons must be fed by force. Strong patients may be allowed a longer time, for many refuse from whim or obstinacy, and hunger will overcome their disinclination. Some patients in a state of acute delirium will take no food; they must be fed at once, and it is important that they should be fed without a protracted and exhausting struggle, for they will resist desperately unless completely overmastered. In almost every case feeding should be done early: the sooner it is done, the shorter will be the period during which it will be required. The various plans to be adopted range from merely feeding with a spoon, as one feeds a child, to sending food down the œsophagus with a tube passed through the mouth or nose, the patient being restrained in a chair or on a bed by attendants or by mechanical means. The mode of feeding varies according to the resistance, and no one method is applicable to every case. There is no need to pass an œsophageal tube down the throat of a man whose resistance is passive and easily overcome; on the other hand, we occasionally find patients of great muscular strength and indomitable will, who can hardly be fed with safety in any way except by the stomach-tube. Of these we may speak first.

In what position are they to be fed, sitting or lying down? If they are to be held by attendants, no doubt the recumbent posture is the one in which the latter can exercise most power. But when a man is so strong that, as we are told, five attendants must hold him, a struggle will not be unattended with danger, for the five are not all acting together, and he gets loose now a leg and now an arm, to the great discomposure of the operator; moreover, this struggle repeated three times a day, soon renders him a mass of bruises. He should be placed in a strong wooden chair, and by sheets wound round his body, arms, and legs, he can be fastened to the chair so completely that he is quite incapable of movement; yet he gets no bruise, and the operator acts upon him free from all inconvenience. Some writers advocate feeding by the nose, and prefer this method to passing a tube through the mouth. It is well fitted for quiet patients, who do not make a desperate resistance and only close their teeth, but it has many disadvantages. A long tube may enter the larynx, or may curl forwards and be caught by the teeth. And if the food is passed into the nose by a short tube or funnel, it is often ejected, and a long time is spent in the operation. The time consumed in feeding by the nose is one of the great objections, and much exhaustion is often thus produced. The only advantage of feeding in this way is that we are not compelled to force open the mouth. This is a work of difficulty, if the patient is strong and his

teeth perfect, unless we are provided with the screw-key invented for this purpose: with this there is little difficulty, and only bungling will injure the teeth or gums, if the patient is properly secured and the head held by an attendant, not between his knees, but in his hands. If the œsophageal tube be of good size it cannot enter the larynx. The wooden termination of the tube must be short, so as to allow of its curving. The operator, standing in front, passes the tube through the hole of the gag, inclining it to the patient's left, so as to avoid the vertebræ. It may be held by the tongue, but at the first inspiration the hold is relaxed, and it glides down the œsophagus. The food may be poured down it by a funnel or pumped down by the pump.

The next class of patients, making less resistance, may be fed by Paley's feeder, a glass vessel with a flattened spout which goes over the tongue; the food is emitted, a little at a time, by means of a spring, and finds its way down the gullet. A certain number of patients may be fed by getting a funnel behind the teeth and pouring food into it; and others by holding the mouth open by means of two spoons, and then pouring food in. The objection to the latter method, and to its many modifications, is the time taken up in the operation, whereby great fatigue and exhaustion are produced.

The food must be in a more or less fluid form, and should consist of soups, milk, eggs, and the like. *See* DIET.

G. F. BLANDFORD.

**FORMICATION** (*formica*, an ant).—An abnormal subjective sensation referred to the skin, which is described as of a 'creeping' character, and as resembling the crawling of ants upon the surface. *See* SENSATION, Disorders of.

**FOURTH NERVE, Diseases of.**—Morbid states of the fourth nerve are shown by *spasm* or *paralysis* of the superior oblique muscle, which it supplies.

*Spasm.*—Little is known of over-action of this muscle, except that clonic spasm in it is the cause of rotatory nystagmus when the quick movement of the upper end of the vertical axis is inwards.

*Paralysis.*—Paralysis is not uncommon. Its usual causes are inflammation of the nerve-sheath from cold; hæmorrhage into the nerve; syphilitic affections of the nerve or of its membranes; cerebral tumours, &c., pressing on or injuring the nerve at its origin from the valve of Vieussens, or in its course around the crus; aneurysm; exostoses or growths in the orbit; and degeneration of the nucleus, in common with the nuclei of the other nerves of the ocular muscles, from which it is occasionally paralysed in tabes, in 'progressive external ophthalmoplegia,' in the rare acute inflammation of the nuclei,

and in sudden lesions in this part of the mid-brain. It has also been known to be involved in the rare affection of the muscles of the eyeball in diphtheritic paralysis.

*SYMPTOMS.*—Even in complete paralysis of the superior oblique muscle there is little obvious deviation of the affected eye. Movement downwards is, however, defective, and therefore diplopia exists when the eye is moved below a line which runs obliquely downwards from the healthy to the paralysed side, through the point of mid-fixation. The uncertainty which results from 'defective projection' of the image formed by the affected eye occurs chiefly in looking down, and in the corresponding downward position of the head. It is common for the first discovery of the defect to be that the patient becomes giddy when he goes downstairs, and sees two flights of stairs before him instead of one. The chief visible defect in movement of the affected eye (examined alone) is downwards and inwards, because it is when the eyeball is moved in this direction that the superior oblique has most influence on the vertical position of the eyeball. In the direct downward movement there is slight convergent strabismus, because the inferior rectus lacks the counteraction to its inward traction, so that its tendency to rotate the globe (lower end of vertical axis inwards) is also unopposed and perceptible. The diplopia which exists when both eyes look down is homonymous—that is, the image formed by the affected eye is on the same side as that eye. The left eye (if affected) being higher than the right, its image (the left) appears lower than the right image. The action of the superior oblique being to move the upper end of the vertical axis of the eye inwards, there is, in its paralysis, an abnormal divergence of the upper ends of the vertical axes, and the double images (being always inverted) will converge; their upper ends being nearer together than the lower. This is due to the obliquity of the false image (*e.g.* the left), and this obliquity is greatest when the eyeball is moved to the left and downwards, because in this position the rotatory power of the superior oblique is greater, and the obliquity is least in looking inwards and downwards. Thus the convergence of the images is greatest when the difference in height is least, and *vice versâ*. When the paralysis of the superior oblique has existed for some time, a secondary contraction of the inferior oblique may cause crossed diplopia on looking upwards.

*TREATMENT.*—The treatment of paralysis of the fourth nerve is in the main that of its cause. When due, as it very commonly is, to syphilis, iodide of potassium in full doses, with or without mercury, is necessary. Smaller doses of iodide with quinine or iodide of iron are also useful for rheumatic paralysis. Blisters to the temple are bene-

ficial in the early stages. A little good, but not much, may be effected by applying the constant current from the eyelid to the forehead (Benedikt), a few cells only being used.

W. R. GOWERS.

**FRAGILITAS CRINIUM** (*fragilitas*, brittleness; *crinis*, the hair).—See **HAIR**, Diseases of.

**FRAGILITAS OSSIUM**.—A diseased condition of the bones, in which they are extremely fragile, so that they are liable to fracture from very slight causes. See **BONE**, Diseases of.

**FRAMBŒSIA** (*framboise*, a raspberry).  
SYNON.: Yaws; Fr. and Ger. *Pian*.

DEFINITION.—An exanthem consisting of an eruption of reddish-yellow tubercles, which gradually develop into moist fungous masses, without constitutional symptoms, or with only such debility as results from ulceration and prolonged discharge.

ÆTIOLOGY AND PATHOLOGY.—Yaws is epidemic among the African race, both in their native country and in the West Indies, especially during childhood—then also premonitory symptoms and pyrexia are more distinct. The disease is contagious and inoculable, and presumably due to a microbe; it has no relationship to syphilis, as was once supposed from a likeness to condyloma. It is not hereditary, and does not recur. ‘Parangi’ in Ceylon, and ‘Button Scurvy’ which occurred in Ireland prior to 1851, were diseases closely similar if not identical; and filthy water and excess of vegetable food appeared to promote them.

SYMPTOMS.—There is a period of incubation of from three to ten weeks in frambœsia, and pains in the limbs and *malaise* always precede the outbreak. The tubercles begin with little or no hyperæmia or tenderness, and range in size from that of a pin’s head to a prominent mass two inches in diameter. Some subside without breaking the cuticle or destroying the derma; others become fungous, somewhat spheroidal masses, pinkish in colour, and with a dirty-yellow, sticky, fœtid secretion. Later on the fungus shrinks and is converted into a brownish scab, or ulceration extends deeply and widely into the tissues. The subsidence of the fungus is succeeded by a pigmented stain, and the healing of the ulcer by a dark depressed cicatrix.

Frambœsia selects by preference the face and neck, the joints, the feet, and the genital regions; and often forms a fringe of tubercles or a prominent ridge around the mouth, the nostrils, or the anus. The mucous membrane near these outlets may be affected in like manner. The lymphatic glands in the vicinity become large and tender.

DURATION AND RESULTS.—The duration of frambœsia averages three months, but may be prolonged to one or more years. Spon-

taneous cure is usual; but in cachectic subjects and when its development is irregular the constitution suffers, the excretions become offensive, and there is extreme prostration. Then the joints swell; ulcers with excessive discharge form around them; and the patient may be crippled for life, or may perish from septicæmia or asthenia.

TREATMENT.—The curative measures of yaws advised by the best authorities are cleanliness, generous diet, saline eliminants, and the local use of carbolic-acid lotions, diluted mercurial ointments, or iodoform. In the later stages constitutional remedies, such as mercury in minute doses, iodide of potassium, and tonics, are indicated. As regards prevention, every hygienic improvement is potent. In some parts of Africa and in Fiji a habit of inoculating the young prevails, so as to procure immunity in adult age, when frambœsia is much more severe.

ERASMUS WILSON. E. D. MAPOTHER.

**FRANCE**, South of.—The eastern part (Mediterranean coast) is dry and bracing, with a very clear atmosphere. The chief resorts in it are CANNES, MENTONE, HYÈRES, and NICE. The western part is moist and mild but variable, the principal places in it being ARCAÇON, BIARRITZ, and PAU. See **CLIMATE**, Treatment of Disease by.

**FRANZENSBAD**, in Austria.—Alkaline sulphated waters. See **MINERAL WATERS**.

**FRECKLES**.—SYNON.: *Lentigines*; *lenticele*; Fr. *Ephérides*; Ger. *Sommersprossen*, *Sommerflecken*.—A freckle is a pigmentary discoloration of the skin, which has received its Latin or technical name from a resemblance in colour, figure, and size to a lentil. It varies in tint from yellow to olive, from brown to black; and is met with on the exposed parts of the skin, particularly the face, neck, and hands, and occasionally on the covered parts of the body (‘cold freckles’). It is usually found in children and women in whom the skin is sensitive and delicate, and has obtained its German synonyms from its greater frequency in the summer season. See **PIGMENTARY DISEASES OF THE SKIN**.

ERASMUS WILSON.

**FRÉMISSEMENT CATAIRE** (*frémissement*, purring; *cataire*, connected with a cat).—A physical sign felt on applying the hand over the region of the heart or great vessels in certain morbid conditions, and compared to the sensation conveyed to the hand by the purring of a cat. This sign is more commonly known as ‘thrill’ or ‘purring tremor.’ See **PHYSICAL EXAMINATION**.

**FREMITUS** (*fremitus*, a low noise).—A group of physical signs, elicited by placing the hand over the respiratory organs, while the patient speaks (*vocal fremitus*), or coughs

(*tussive fremitus*); or in certain morbid conditions when the patient simply breathes (*rhonchal* and *friction fremitus*). A fremitus may sometimes also be felt over the cardiac region in connexion with the movements of the heart, when the surfaces of the pericardium are much roughened. Another form of fremitus is a peculiar sensation called *hydatid fremitus*, which may be elicited by a special mode of percussio over hydatid tumours in some cases. See PHYSICAL EXAMINATION.

**FRICITION.**—SYNON.: Rubbing; Fr. *Friction*; Ger. *Reibung*.

**DEFINITION.**—By friction we mean surface-rubbing, as distinguished from *shampooing*, or, as it is sometimes called, *medical rubbing*, a process of manipulation by which deep pressure is made upon the muscles.

**APPLICATIONS AND USES.**—Friction is usefully employed over the surface of a limb, or over the trunk, for a variety of purposes. It is especially useful when the circulation is enfeebled, either by the external application of cold, amounting, when in a severe degree, to frostbite, or in cases of paralysis. The effect is still further increased by the use of various stimulating liniments, more especially when it is desirable to excite a certain amount of counter-irritation over a large cutaneous surface, for the relief of congestion or inflammation of internal organs.

Another object with which friction is largely employed in medicine, is to facilitate the absorption and introduction into the system of various remedial agents applied externally. By this means gastric irritation and disturbance are avoided, and the effects of the remedies upon the system can be more closely watched and regulated. In this way mercury is frequently introduced into the system by the process commonly spoken of as *rubbing in*, and salivation can be more easily avoided or checked at its commencement than when mercury is administered by the mouth. The part of the body selected for this purpose is that along the inner side of the thigh up to the groin; and mercury, in the form of ointment, rubbed in every night and morning, will generally affect the system in a few days.

Another instance of friction is to be found in the fattening of children by the process of rubbing in oil—fresh neat's-foot oil is the best—every night and morning, over the chest, abdomen, arms, and thighs. Emaciated children, thus treated, gain in weight by the absorption of the oil; and not only do they fatten, but their general nutrition and health are improved, often with the diminution of glandular swellings and the disappearance of coughs.

WILLIAM ADAMS.

**FRICITION-FREMITS.**—The form of fremitus produced by the rubbing together of surfaces roughened by various morbid conditions, as of the pleura in breathing, or of the pericardium from the movements of the heart. See FREMITUS; and PHYSICAL EXAMINATION.

**FRICITION-SOUND.**—A physical sign, heard on auscultation, and due to the rubbing against each other of serous surfaces that have lost their natural smoothness and moistness from any cause. See PHYSICAL EXAMINATION.

**FRIEDRICHSHALL**, in Germany. Sulphated waters. See MINERAL WATERS.

**FROSTBITES.**—DEFINITION.—The local effects of severe or extreme cold upon any exposed parts or tissues of the body, more serious than those described as 'chilblains.'

The parts of the body most frequently affected by frostbites are the toes and neighbouring parts of the lower extremities, the fingers and hands, the nose, and the ears, all because of their especial liability to exposure, and the first named because also of their remoteness from the heart, and other disadvantages in their blood-supply.

By far the largest proportion of cases occur among men in or about the prime of life: first, because from the nature of their occupations they are most liable to exposure; and secondly, because from constitutional vigour they better withstand any immediately fatal general effects of exposure, and so survive with local damage.

**SIGNS AND SYMPTOMS.**—The signs and symptoms of frostbite vary in manifestation, in rapidity of occurrence and in succession, with the degree of cold, the medium and mode of application, and the duration of exposure, as also with the general condition of the sufferer. They may, however, be thus described: Transient redness of the part affected, accompanied by hyperæsthesia and tingling sensations, is more or less quickly followed by purplish lividity with diminished sensibility. Blanching, with numbness, supervenes. Next, congelation takes place, signalled by whiteness, hardness, and absolute insensibility. Lastly, the freezing process may extend more and more deeply, and be continued until all the tissues are literally 'frozen to death,' and their recovery is impossible. 'Dry gangrene' is then established, and the parts affected shrivel, dry up, and blacken. If the last stage indicated has not been reached, more or less complete recovery may be effected sooner or later. But 'moist gangrene' is liable to supervene, from inflammation after partial restoration of the circulation in the more severe cases; and other, though less serious trophic lesions, from similar cause, frequently occur in the milder

cases. Parts that have not been actually frozen, but have been subject to repeated or long exposure, may become gangrenous, or may suffer from more or less permanent impairment of nutrition and function, such effects being due to organic damage to the nerves and blood-vessels. See GANGRENE.

**TREATMENT.**—The treatment of a frost-bitten part essentially consists in such measures as are calculated to restore warmth, and re-establish the circulation. The greatest care, judgment, patience, and perseverance are requisite, or the attempts made may only render the mischief worse. The process must be gradual and slow to be safe.

The patient must not be brought at once into a warm room or near a fire, but should be kept in a moderately cold atmosphere, and in a recumbent position. The part affected should be somewhat raised, and gently rubbed with snow or bathed with ice-cold water for some time. Very gradually the temperature of the water may be raised, or oil may be substituted. Later, dry friction may be employed. The frictions should be carried considerably above the part obviously affected. From time to time the affected parts may be lightly enveloped in fur or wool, and the frictions repeated at intervals. After apparent restoration has been effected, treatment by friction, with or without some mildly stimulating liniment, should be persevered with day by day for some considerable period, and the part should be warmly clad. Consecutive inflammation of the skin, with vesication or superficial sloughing, occurs in some cases; in other cases the deeper structures also suffer, and moist gangrene results. Such conditions are especially liable to occur in cases in which the change from cold to warmth has been too rapid. They are to be treated *secundum artem*.

If, in spite of all efforts, restoration cannot be effected, and any part remains cold, dead, and gangrenous, or if from consecutive inflammation moist gangrene should supervene, it is better to wait for complete or almost complete separation of the dead structures before proceeding to amputation or other operative measures. The adjoining parts remain for very long in such depressed vital condition that, if cut through, they are little likely to heal favourably, and very often slough after fresh injury inflicted by operation wounds.

Parts that have been severely frostbitten, even if preserved, are liable to suffer permanently from more or less serious impairment of nutrition, due probably to damage done to the trophic nerves as well as to the blood-vessels. The skin of such parts is often discoloured, and in some cases is hyperæsthetic or painful, and in others more or less numb. It is prone to become inflamed and to ulcerate; and if ulcerated or wounded, healing takes place very slowly as a rule.

Protection against exposure to cold and injury should be carefully and constantly afforded.

For the constitutional and general treatment of the frostbitten, see COLD, Effects of Severe or Extreme.

ARTHUR E. DURHAM.

**FUMIGATION** (*fumigo*, I smoke).—**SYNON.**: Fr. *Fumigation*; Ger. *Beräucherung*.

**DEFINITION.**—A mode of employing certain medicinal agents, which are capable of being volatilised by heat, the vapour being allowed to escape into an apartment, or to come in contact with articles of clothing and other objects, for purposes of disinfection; or being allowed to act upon the surface of the body for therapeutic purposes. The chief agents which are thus used are sulphur and mercury.

**MODE OF APPLICATION AND USES.**—*Sulphur.*—The mode of using sulphur as a disinfectant is explained in the article **DISINFECTATION**. The sulphurous acid may also be brought into contact with the body, sulphur being burnt in a suitable apparatus. It is sometimes thus used for the cure of scabies and other affections.

*Mercury.*—Mercurial fumigation, general or local, has long been employed in the treatment of syphilis, and many different preparations of mercury have been used in this way.

*General mercurial fumigation* is now usually effected by exposing the body to the fumes of calomel mixed with steam, the steam being added with the twofold object of inducing gentle perspiration, and of rendering the mercurial fumes less irritating to the respiratory passages. The best form of mercurial vapour-bath is that recommended by Mr. Henry Lee. The apparatus consists of a spirit-lamp which is enclosed in a case of wire gauze, on the top of which is a small plate surrounded by a porcelain trough. One ounce of water is poured into the trough, and the lamp is then lighted. When the water begins to boil, from 20 to 30 grains of resublimed calomel are spread on the plate, and the apparatus is placed between the patient's legs as he sits on a chair undressed, but surrounded by a moleskin cloak long enough to reach the ground. The cloak is tied round the neck, but kept away from the rest of the body by a cane hoop. If it be thought desirable that the vapour should be inhaled, the slit of the cloak may be opened slightly from time to time. The patient should not be alone during the bath, as it sometimes causes faintness. When the calomel is exhausted, which usually takes about a quarter of an hour, the patient goes to bed wearing the cloak as a nightdress. The bath may be repeated every night, or less often, according to the case and the effect

produced. The state of the gums must be closely watched, and the dose of calomel regulated according to circumstances.

General mercurial fumigation has been employed in all stages of syphilis, but is probably best adapted for the secondary manifestations, especially the widely spread dry eruptions. It may be tried whenever mercury is not well borne by the stomach. See SYPHILIS.

*Local* mercurial fumigation has been found serviceable in treating obstinate affections of the skin and mucous membrane, in the later as well as in the earlier stages of syphilis. From 3 to 5 grains of calomel is the usual quantity for each fumigation.

GEO. G. GASCOYEN. ARTHUR COOPER.

**FUNCTIONAL DISEASES.**—A class of diseases in which no anatomical or structural change can be detected to account for their presence. See DISEASE, Classification of.

**FUNGI, Diseases due to.**—See PARASITES, Vegetable; and MUSHROOMS, Poisoning by.

**FUNGOID** (*fungus*, a mushroom).—A term applied to superficial granulations and morbid growths, especially those of a malignant nature, when they sprout rapidly and assume an appearance somewhat like a mushroom. See CANCER; and ULCER AND ULCERATION.

**FUNGUS-DISEASE OF INDIA.**  
SYNON.: Madura Foot; Mycetoma; *Morbus Tuberculosis Pedis*; Fr. *Dégénérescence Endémique des Os du Pied*; *Pérical*.

**DEFINITION.**—A diseased condition of the hands and feet, occurring in India, characterised by enlargement and distortion of the affected extremity, due to thickening of the cutaneous tissues, with degeneration and subsequent fracture of the osseous structures. Two forms of the malady are described—the one, the pale or ochroid form, characterised by the presence of minute globular fatty particles like fish-roe, and, though very rarely, by the existence of minute pink concretions not unlike red-pepper granules; the other, the melanoid or dark form, characterised by the existence of black or dark brown masses, varying in size from that of a grain of gunpowder to a walnut, and composed of fungoid filaments, cells, and pigmentary deposit.

**DESCRIPTION.**—This remarkable disease had not been observed beyond the limits of Hindostan, until a solitary case of it was recorded within the last few years in Italy. In India it has rarely been seen to affect any but natives. No case of a European or half-caste has been recorded as suffering from a typical form of the malady. The foot has been observed to be affected more often than the hand; hence it was common formerly to find

the malady referred to as one peculiar to the foot. It has been recognised as a distinctive disease in India for more than thirty years, and was described by Goodfrey, of Madras, in the *Lancet* in 1846, and by Eyre in the *Indian Annals of Medical Science* in 1860. It is to Dr. Vandyke Carter, however, that we are chiefly indebted for what is known of the malady, clinically and pathologically, and his writings date as far back as 1860. His published memoir on the disease (*Mycetoma, or the Fungus-disease of India*, 1874) contains a summary of all that had been written regarding it up to the period of publication. The foot or hand affected with the disease presents appearances not unlike those observed in some forms of caries—especially caries of scrofulous origin. When the foot is affected, it is found to be considerably increased in circumference, the enlargement seldom extending far beyond the ankle; the foot is prone to run in a line with the leg, and may be everted or inverted. It is not, however, in the aspect presented by the limb that the leading peculiarity consists, but in the character of the discharges from the sinuses, the openings of which are scattered all over the surface of the affected tissue. It is this peculiarity which led Dr. Carter to separate the disease into two forms—(1) the 'pale' or 'ochroid,' the discharge of which consists of whitish-yellow roe-like bodies of about the size of millet-seed; and (2) the 'dark' or 'melanoid,' so called from the dark brown or even black granular bodies that constantly escape through the sinuses, not unlike grains of coarse gunpowder. The first form may be said to present two or three varieties, according to the modified character of the discharges; these will be referred to more definitely farther on.

The malady would appear to occur more frequently in Madras, Bombay, and the more westerly and north-westerly parts of India than in Bengal proper. This, however, seems to apply more especially to the dark variety; for, whilst no well-authenticated case of this form has been recorded as having manifestly originated in the last-named province, cases of the pale variety are not infrequent. So far as the foot is concerned, the pale form is apparently the one most commonly met with all over India. As regards the hand, however, this would not seem to be the case, for, whilst the writers have had the opportunity of examining two or three hands affected with the dark variety, they have not seen one affected with the pale; nor can they find any account of such a case having been witnessed. The distortion of the hand affected in this manner is very peculiar—it is shortened and thickened, owing to the destruction of the carpus and metacarpus, and the consequent irregular tension of the extensor and flexor tendons.

**ANATOMICAL CHARACTERS.**—On our laying open a characteristic specimen of the dis-

ease, the bones are found to be extremely softened, so that they can readily be divided by means of a common knife. The interior of the hand or foot is occupied by a series of sharply defined cavities, some quite isolated, but the majority communicating with one another and with the exterior, by a series of complex channels, or sinuses, containing glairy fluid and solid concretions in various proportions. Both cavities and channels are lined by a dense glistening membrane, composed of white fibrous and elastic tissues. The surrounding tissues are generally in a very fatty condition, and, where the disease is of long standing, are more or less completely blended into an indistinguishable mass. So far a common description is applicable to both forms of the disease; but on proceeding to the consideration of the contents of the cavities, great differences present themselves.

*Pale form.*—The pale or ochroid form is capable of subdivision into several varieties, according to the nature of its morbid products. In the commonest and most characteristic variety the cavities and channels contain masses of spherical bodies like fish-roe, of a pinkish yellow or white colour, surrounded by gelatinous glairy matter. In certain cases, however, the roe-like bodies are almost or entirely absent, and the gelatinous matter and liquid oil are generally diffused throughout the tissues. In a third and very rare variety the section looks as though besprinkled with grains of red-pepper, from the presence of innumerable minute concretions of a bright red hue.

*Dark form.*—The appearances presented in the dark form of the disease are strikingly different. Here, in place of the roe-like bodies of the previous form, the cavities and channels contain masses of a dark brown or black colour. These masses vary greatly in size, some not being larger than the normal fat-lobules surrounding them, others attaining to the size of a small orange. The larger masses greatly exceed any of the roe-like masses of the pale variety in size, and their consistence is also much firmer than that of the latter. They are tuberculated on the surface, and closely resemble truffles in appearance. On section, they present a more or less distinctly radiating structure, and the interior is generally somewhat lighter in colour than the tuberculated exterior coating. In some cases they are tightly fitted into the cavities in which they lie, but in others they lie loose, and are surrounded by a certain amount of gelatinous matter. The amount of the latter present is, however, much less than in the pale form.

The masses of morbid material in both forms are primarily situated in spaces normally abounding in fat. Long series of them are frequently interpolated among the loculi in the subcutaneous tissue, between healthy

fat-lobules; others occupy the interior of the bones; and a third series are developed in the pads of fat lying around muscles and tendons. The muscles and tendons in such cases may frequently be found quite intact, although surrounded by masses of the morbid material. Due to this persistence, fracture and crushing of the softened bones often occur, and it is on this that the distortion of the affected part is in many cases in great measure dependent.

*Minute characters of the morbid products.* The roe-like particles are composed of a nucleus of granular, waxy consistence, surrounded by a fringe of radiating crystals. They appear to be almost entirely composed of fatty matter, and no traces of the presence of parasitic organisms of any kind can be detected in them. The bright red particles occurring in certain cases of the ochroid form are concretions, consisting in great part of phosphates and carbonates, and containing a considerable proportion of iron.

The dark masses present in the other form of the disease are of much more complex structure. In all, or almost all, cases they contain septate fungoid filaments in greater or less proportion. These are sometimes difficult to distinguish, but may generally be detected by allowing portions of the material to soak for some days in liquor potassæ. The proportion which the filaments bear to the entire mass, when thus separated, is in any case very small, and in some cases extremely so, for on the completion of the soaking only a very small quantity of colourless flocculi, consisting of masses of branched filaments mixed with empty cyst-like cells, is left behind in the fluid. The latter has assumed a brown colour from the solution of the dark mass. The filaments and cysts (*see the accompanying figure*), in so far as tests have yet determined,

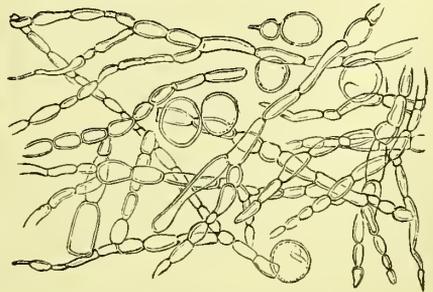

FIG. 58.—Fungoid Filaments and Capsules obtained after prolonged maceration in caustic potash of the dark masses of fungus-disease.  $\times 500$ .

are indistinguishable from undoubted fungal elements. They are, as a rule, quite empty, and show no signs of growth, or indeed of life. The basis in which they are imbedded

varies greatly in different cases. In some instances it is soft and contains much oily matter, but in the more advanced cases this is almost absent. It is then only soluble by means of alkalis. The ash consists mainly of calcium phosphate, and is red, from the presence of oxide of iron.

The fungoid filaments have never yet been shown to be capable of any further development. All attempts at cultivation have failed in causing them to assume any form by which their true nature and relationships may be determined. They have never given any unequivocal signs of life external to the body, even when exposed to conditions favourable to the growth of fungi, as demonstrated by the development of various extraneous moulds upon the surface of the black masses themselves, or on the media in which they were immersed.<sup>1</sup>

**SYMPTOMS.**—Dr. Carter writes: 'As a rule the local indications of this disease are the same for all its forms; for commonly it is not possible to discriminate the several varieties by simple inspection or bare clinical history of the case.' The statements made by the patients as to the mode of origin and progress of these complaints are very various; but, taken generally, they seem to imply that the symptoms are analogous to those usually observed in deep-seated disease of the osseous and adjoining tissues. Eventually a more or less hard lump is felt in the sole of the foot or palm of the hand, or in several places. Generally one or more abscess-like formations occur; and several sinuses are ultimately established, the latter, as a rule, presenting a peculiar mammillated appearance—the 'tubercles,' apparently, of earlier writers. Along with these changes, enlargement and distortion of the affected member take place, but unaccompanied with severe pain. Discharges set in, more or less offensive, according to the nature of the subjacent degeneration, and the limb becomes not only useless, but a burden to its owner. In this manner the sufferer may go on for from one to fifteen or more years, unless relief be sought in a surgical operation.

**COURSE AND DURATION.**—Both forms of fungus-disease run a very chronic course, and often without very materially affecting the general health of the patient; in some cases, however, great emaciation accompanies the disease. With regard to the duration of the malady, it may be stated that cases have been recorded as having existed for various periods up to twenty-six or even thirty years.

**PATHOLOGY.**—The occurrence of the fungoid filaments in the products of the dark variety of the disease has caused many authors to

regard them as the essential cause of it. There are, however, good grounds for rejecting such a conclusion. Had the dark form of the disease been the only one with which we were acquainted, there might have been some cause to regard it as due to parasitic agency. When, however, we find that the pale form, whilst causing all the important lesions present in the other, shows a total absence of all fungoid elements in its products, we are forced to regard such elements as of secondary importance. The only means of overcoming this objection would be a demonstration that the products of the pale form are due to a degeneration of the black matter, in the course of which the fungoid elements disappear. No such demonstration has been given, and, on the contrary, it has been shown that each form is capable of running an entirely independent course, the gradual transformation of the normal fat having been traced in the one case to the production of the roe-like particles, and in the other to that of the black masses in which the fungoid elements are imbedded. Were the pale form the only one known, the disease might be described as a mere degeneration of the fatty tissues, with the results consequent on the presence of the morbid products of the process in the surrounding parts; but this explanation, although so far applicable to the dark form, throws no light on the source of the fungoid elements. They are present in masses which are entirely isolated in the tissues, having no communication with one another or with the exterior. There is no evidence of their passage from one cavity to another—on the contrary, they are absolutely limited to the contents of the cavities, the membranous walls of the latter and the intervening tissues never showing any traces of a spreading mycelium, or of any other fungal elements.

Assuming the filaments to be of undoubted fungal origin, the facts point rather to their simultaneous and independent development in multiple centres, than to their spread from one to another. The fact of the necessity of a suitable soil or nidus, in addition to the mere presence of germs, in order to secure the development of organisms, is generally accepted. That germs of most various kinds must constantly be introduced into the blood, is a self-evident fact. Putting their introduction by means of the lungs out of the question, their constant introduction from the intestinal canal can hardly be denied. It can be demonstrated that the intestinal contents abound in vegetable organisms—spores, bacteria, &c.—in a living condition. As it is an ascertained fact that solid particles of inorganic matter of far larger size than many of these germs can enter the circulation, it can hardly be denied that the latter may, and indeed must, enter also. So long as such bodies do not meet with con-

<sup>1</sup> The later researches of Dr. Carter and others (*Lancet*, July 2, 1892, p. 18) indicate that Fungus-Disease is identical with Actinomycosis. See ACTINOMYCOSIS.—EPITOR.

ditions favourable to development, they are no doubt destroyed and utilised by the living matter of the blood and other tissues. If, however, they are deposited in a medium favourable to them, they will grow and undergo such development as they are capable of. The morbid products of the disease here described are practically dead material, external and extraneous to the body, and it has been experimentally demonstrated that, when removed from the body, they form a basis capable of supporting the growth of fungal organisms. Given these two conditions—the constant presence of germs in the circulation, and the possession of a suitable soil for fungi, and the difficulty of accounting for the presence of fungal elements in the latter appears in great part to be removed.<sup>1</sup>

**TREATMENT.**—There are no instances recorded of a spontaneous cure having been effected, nor have remedial applications proved of material permanent value in either form of the disease. Removal of all the diseased tissue, by amputation of the affected extremity, is the only remedy which meets

with general approval. The subsequent treatment resolves itself into that of an ordinary surgical operation.

D. D. CUNNINGHAM. T. R. LEWIS.

**FUNGUS HÆMATODES** (*fungus*, a mushroom; *αἷμα*, blood; and *εἶδος*, form).—A synonym for soft malignant growths, which are exuberant and highly vascular, and therefore peculiarly liable to bleed. See **CANCER**; and **TUMOURS**.

**FURED, in Hungary.**—Weak alkaline saline waters. See **MINERAL WATERS**.

**FURFUR** (Lat. bran).—A bran-like desquamation of the skin, met with in several cutaneous diseases, more especially pityriasis, psoriasis, and ichthyosis: scurf; dandruff. See **SKIN, Diseases of**.

**FURFURACEOUS** (*furfur*, bran).—A term applied to conditions in which the epidermis is shed in the form of bran-like scales. See **FURFUR**.

**FURUNCULUS** (Lat. a little rascal, dimin. of *fur*, a thief).—A synonym for boil. See **BOIL**.

## G

**GADFLY.**—The popular name for a genus of insects whose larvæ infest man and the lower animals. See **CÆSTRUS**.

**GALACTAGOGUES** (*γάλα*, milk; and *ἄγω*, I move).

**DEFINITION.**—Agencies which increase the secretion of the mammary gland.

**ENUMERATION.**—The most common galactagogues are: Mental Emotions; Local Nervous Stimulation; Warmth; good Food; Alcohol; Jaborandi; the fresh leaves of the Castor-Oil plant; Tonics; and Electricity.

**ACTION.**—When we consider how powerfully mental processes may affect the activity of nerves supplying the secreting structure of glands, we can understand how these may influence the secretion of milk, as of the sweat, the saliva, and the tears. The maternal feelings of joy, as well as the reflex stimulation of the infant's lips, act most rapidly in developing the functions of the breast. Warmth and good diet also play their part in the process. Alcohol in the form of malt liquors, or malt-extract, is a useful adjunct; and so are such tonics as iron, which counteract in some measure the severe drain on the constitutional resources. Little use has yet been made in actual practice of those drugs

which are specially credited with galactagogue properties; but we are told on good authority that a poultice made of the fresh leaves of the castor-oil plant, aided by teaspoonful doses of a fluid extract prepared from the same, has a markedly stimulating influence on the mammary secretion. Belladonna is well known to dry up the milk; and jaborandi, which is its antagonist in so many respects, has been shown to have here also a directly opposite effect, and to be a drug of which further use may yet be made when we wish to excite or re-establish the proper functions of the mammary gland.

ROBERT FARQUHARSON.

**GALACTIDROSIS** (*γάλα*, milk; and *ἰδρῶς*, perspiration).—A term signifying milky perspiration. See **SUDORIPAROUS GLANDS, Disorders of**.

**GALACTORRHŒA** (*γάλα*, milk; and *ῥέω*, I flow).—An excessive flow of milk. See **LACTATION, Disorders of**.

**GALL-BLADDER AND GALL-DUCTS, Diseases of.**—These affections may be considered in the following order: (1) Catarrh; (2) Inflammation and its Results; (3) Stricture; (4) Dilatation; (5) Cancer; (6) Foreign Bodies; (7) Enlargement

<sup>1</sup> See footnote on preceding page.—EDITOR.

of the Gall-bladder; (8) Perforation; and (9) Biliary Fistula.

1. **Catarrh of the Bile-passages.**—This disease very rarely gives opportunities for examination after death. At the period after death at which it is customary to make *post-mortem* examinations in this country, all redness of the duct has usually disappeared; and there are left only swelling and pallor of the mucous membrane, which is covered with a tenacious glassy or purulent secretion. By this swelling and secretion the bore of the duct is often greatly narrowed; and it can be seen that no bile has passed over it for some days, as all colour has disappeared from the affected part of the tube. In judging of this, however, no pressure must have been made upon the gall-bladder during the earlier part of the examination. These appearances are most pronounced in the common duct and the gall-bladder; they are gradually lost in the hepatic duct and its branches in the liver. The process seems most intense at the duodenal end of the gall-duct, and the orifice of the papilla itself is often found plugged by mucus, an appearance which certainly favours the notion that the catarrh is propagated from the stomach and duodenum. This is believed to be the commonest source of catarrh of the bile-ducts. It is also seen in nutmeg-liver and cirrhosis; and a tendency to chronic catarrh is set up by the presence of foreign bodies in the ducts, such as gall-stones.

**SYMPTOMS.**—Jaundice is often the first symptom which draws the attention of the patient to his health in a case of catarrh of the bile-ducts, although in a certain number of cases this is preceded by symptoms of gastric disorder, such as vomiting or sense of sickness, loss of appetite, and furred tongue; or, on the other hand, by diarrhoea. The jaundice lasts usually about three weeks, sometimes as much as six or eight weeks. After this, suspicion should be aroused whether something more than a simple catarrh be not present.

**DIAGNOSIS.**—The diagnosis depends upon the absence of any physical signs indicating organic change in the liver; and on the presence of gastric symptoms. Thus nearly all cases of simple jaundice are diagnosed by some physicians as cases of catarrh of the bile-ducts. As the greater number of the patients recover, very few opportunities are given for verifying this diagnosis; but in those which have been examined, plugs of mucus in the ducts have not infrequently been found. The catarrh caused by gall-stones is lost in the jaundice and pain associated therewith.

**TREATMENT.**—The treatment should at first be directed to the gastric symptoms, beginning with a purgative, followed by a course of effervescent alkaline medicines, and restricted diet. Later on, dilute nitro-hydro-

chloric acid taken before meals is often very useful. Daily enemata of one or two quarts of water, at a temperature of from 60° to 90° F., to be retained as long as possible, have been recommended.

2. **Inflammation and its Results.**—In some cases of typhus and typhoid fever, and in other typhoid states, the gall-duct and gall-bladder become *ulcerated*, or filled with purulent fluid, or covered with *croupous exudation*. The same thing may happen when gall-stones are impacted in the ducts. The gall-ducts are sometimes *obliterated* by fibrous bands passing over them. Sometimes they suffer a congenital obliteration by the over-growth of the fibrous tissue around them.

3. **Stricture.**—Stricture of the gall-duct is occasionally met with. Usually it is associated with the presence of gall-stones. It would seem most probable that it arises from inflammation and ulceration of the duct produced by the transit or impaction of calculi. On the other hand, it is possible, though not probable, that it may be primary, and by impeding the escape of bile give rise to gall-stones. Stricture of the gall-duct causes dilatation of the ducts or gall-bladder behind.

4. **Dilatation.**—The gall-ducts and gall-bladder become dilated whenever there exists an obstruction, either pressing on the ducts from the outside, or formed within them. The first result is dilatation of the ducts behind the obstruction. The gall-bladder becomes much dilated, often filled with a thick green bile. If the obstruction last long, the coloured part of the bile is absorbed, and its place taken by a colourless fluid, either viscid or limpid. This fluid contains neither bile-pigment nor bile-acids, is often albuminous, and contains abundance of mucus. The ducts outside the liver may be enormously distended. It is common to see them as big as the middle finger. Within the liver they are also dilated, but not to so great a degree; and they are more dilated on the left than on the right side. The dilatation of the ducts may become cystic, and sometimes moniliform. The writer (J. W. L.) has always been able to find columnar epithelium in these dilated ducts. In some cases of long-continued obstruction, the contents of the bile-ducts become colourless; in other cases, purulent; and small abscesses form around the bile-ducts, and open into them. These abscesses may be multiple; or, more commonly, only a single large one is formed. The abscess or the dilated gall-ducts may rupture into the peritoneum, and cause fatal peritonitis.

5. **Cancer.**—Primary cancer of the gall-ducts and gall-bladder is sometimes met with; or they may be affected secondarily.

6. **Foreign Bodies.**—Foreign bodies are occasionally met with in the gall-ducts. The most common of all are, of course, *gall-stones*. Much less common are entozoa,

such as the *Distoma hepaticum*, *hydatids*, or the two kinds of *ascarides*, especially lumbrici.

**SYMPTOMS.**—In all these different morbid states it is usually only possible to say at the bedside that the large bile-ducts are obstructed; a more complete diagnosis is commonly impossible. Jaundice is an important symptom, as without it disease of the bile-ducts cannot be diagnosed. It is commonly very intense, the urine being deeply coloured, and the fæces quite colourless. The enlargement of the liver, if present, is commonly uniform, the surface being smooth, and the edges well-defined. The gall-bladder may often be felt at the edge of the right lobe as a rounded tumour; this is then a sure sign of the obstruction of the gall-ducts. In simple diseases of the gall-ducts there is an absence of splenic tumour, of ascites, and of other symptoms of portal obstruction. In many cases, however, diseases of the liver and of the gall-ducts are so intimately bound up together, that they cannot, during life, be separated.

**PROGNOSIS.**—The prognosis, if simple catarrh of the gall-ducts and gall-stones can be excluded, is unfavourable.

**TREATMENT.**—The treatment must be conducted on general principles.

**7. Enlargement of the Gall-bladder.** The gall-bladder cannot be felt in health during life. But it may often readily enough be made out where there exists any obstruction in the common or cystic duct, so that it becomes distended with fluid. It may also be felt when the walls become fibrous or calcified, or the seat of cancer; or when its cavity is filled with gall-stones. A tumour may then be felt under the border of the right lobe of the liver, in the situation of the gall-bladder. When filled with fluid, a rounded, sometimes oblong, sometimes pear-shaped tumour is felt; in other cases it has an irregular shape, or a somewhat rounded outline. The gall-bladder usually enlarges in a direction obliquely downwards and forwards in a line which, drawn from the tenth costal cartilage, crosses the middle line a little below the umbilicus (Mayo Robson). A greatly distended gall-bladder has been mistaken for ascites, and tapped. The diagnosis depends chiefly on the situation of the swelling, and even then the distended gall-bladder may be mistaken for hydatid disease of the liver-substance or of the omentum, or for a tumour of a neighbouring organ, especially the right kidney, which has pressed against the liver. The difficulty of the diagnosis is much increased if the liver be moved from its natural place, for then the position of the gall-bladder becomes uncertain. Bamberger says he has often mistaken a softened cancerous nodule of the liver for a distended gall-bladder. If it be certain that a fluctuating tumour be the gall-bladder, and no jaun-

dice be present, a diagnosis may safely be made of *hydrops cystidis felleæ*, or dropsy of the gall-bladder; but if jaundice be present, or if the tumour do not fluctuate but appear solid, there are then no definite rules for diagnosis: all depends upon the surrounding facts of the case. Dropsy of the gall-bladder is not a dangerous disorder, and requires no treatment; while the prognosis and treatment of the other states depend entirely on their respective causes. Surgical treatment is now extensively employed.

**8. Perforation.**—Perforation of the gall-bladder or of the gall-ducts is generally the result of ulceration, due to gall-stones, inflammation, and other causes. Fatal peritonitis ensues if the perforation occur into the abdominal cavity. Frequently, however, previous adhesions have been formed between the biliary reservoir or duct and the neighbouring organs, as the intestine, or the abdominal wall, and the result of this is—

**9. Biliary Fistula.**—This may exist between the gall-bladder or gall-ducts and the surface of the body, the stomach, colon, or duodenum. Very rarely gall-stones find their way into the urinary tract.
